Challenges of Diagnosing Viral Anterior Uveitis

Fahriye Groen-Hakan, MD, Kalpana Babu, MD, PHD, Ilknur Tugal-Tutkun, MD, Kessara Pathanapithoon, MD, PHD, Joke H. de Boer, MD, PHD, Justine R. Smith, FRANZCO, PHD, Jolanda D.F. de Groot-Mijnes, PHD, and Aniki Rothova, MD, PHD

ABSTRACT

The viral causes of anterior uveitis (AU) emerged with the use of novel molecular diagnostic tests and serologic tests adapted for small volumes (Goldmann-Witmer Coefficient). The viral causes of AU may be underestimated, and some of the presumed idiopathic AU cases will probably be proven to be of viral origin in the coming years. So far, a viral origin of AU was suspected in patients who presented with unilateral hypertensive AU. It is not clear which clinical presentations should raise a suspicion of viral etiology. There is an overlap in the clinical manifestations of AU caused by viruses and other non-viral forms of AU. A viral cause of AU should be suspected in patients with unilateral AU, exhibiting small or medium sized KPs, some form of iris atrophy, high IOP and early development of a cataract and the definitive diagnosis can be proven by aqueous humor analysis.

Keywords: Anterior Uveitis, Clinical Features, Diagnosis, Viral Uveitis

INTRODUCTION

Anterior uveitis (AU) is the most common anatomic type of uveitis encountered by ophthalmologists. Though traditionally reported that most cases of AU are of unknown origin, the specific etiology may presently be documented in a substantial number of cases. The AU has multiple causes and in adults, the most frequent entity is Human Leukocyte Antigen-B27 (HLA-B27)-associated uveitis, whilst juvenile idiopathic arthritis (JIA)-associated AU is the most frequent occurring in children. The viral causes of AU emerged with the use of novel molecular diagnostic tests and serologic tests adapted for small volumes (Goldmann-Witmer Coefficient; GWC). The viral causes of AU may be underestimated, and some of the presumed idiopathic AU cases will probably be proven to be of viral origin in the coming years. The most common AU-inciting infections and associated systemic diseases are given in Tables 1 and 2. Herpes simplex virus (HSV) and varicella zoster virus (VZV) represent common viral causes of AU in the West, whilst cytomegalovirus (CMV) is more frequent in Asia. In contrast to decreasing prevalence of rubella virus (RV)-associated AU in vaccinated populations, novel uveitis entities, such as Ebola virus and Zika virus-associated uveitis, were discovered during recent epidemics.
So far, a viral origin of AU was suspected in patients who were presented with unilateral hypertensive AU. Further, distinctive signs were described for separate viruses, but it is not clear which clinical presentations should raise a suspicion of viral etiology. Herein we summarize the typical clinical manifestations of the common types of AU encountered in clinical practice and attempt to delineate the clinical characteristics commonly seen in patients with viral AU.

### CLINICAL FEATURES OF COMMON NON-INFECTIOUS ANTERIOR UVEITIS ENTITIES

#### Human Leukocyte Antigen-B27-Associated Anterior Uveitis

Human leukocyte antigen-B27-associated uveitis is characterized by unilateral alternating acute non-granulomatous AU with marked fibrinous reaction or hypopyon Figure 1, occurring typically in young adults, and has a frequent association with seronegative arthritic syndromes, of which the most prevalent is ankylosing spondylitis. Patients typically present with sudden onset of a classic triad of pain, redness, and photophobia. The main external signs are conjunctival and perilimbal redness. The anterior segment shows diffuse cells and flare in the anterior chamber; sometimes with cells adhering to corneal endothelium, but large keratic precipitates (KPs) are not present. Intraocular pressure (IOP) often decreases in the acutely inflamed eye, but in severe cases, a fibrinous exudate and posterior synechiae may occlude the entire pupil leading to iris bombé and dramatic elevations in IOP. Less typical presentations involve posterior segment involvement including vitritis with or without pars plana exudates, optic disc swelling or papillitis, and cystoid macular edema (CME). Chronic AU as well as episcleritis and scleritis are less typical.

#### Sarcoidosis-Associated Anterior Uveitis

Sarcoidosis may be associated with all anatomical types of uveitis. Anterior uveitis due to sarcoidosis is typically seen in young adults, more often in non-Caucasian races. The patient with sarcoidosis-associated AU may present with a few complaints and a relatively white eye. Raised IOP is often noted. Sarcoidosis-associated AU shows predominantly bilateral granulomatous inflammation with large fatty KPs located in the inferior part of the cornea (Arlt’s triangle, Figure 2) and has sometimes also characteristic granulomatous lesions on the iris, such as Koeppen and/or Busacca nodules. Posterior and anterior synechiae are common in this entity, and may be associated with the development of glaucoma. Cystoid macular edema is a common complication of sarcoidosis-associated AU. The presence of systemic sarcoidosis in a patient with uveitis of unknown origin is generally accepted as a confirmation of sarcoidosis-associated AU. Ocular signs suggestive of sarcoidosis were assessed by the initiative to define clinical criteria for

the diagnosis of intraocular sarcoidosis (International Workshop on Ocular Sarcoidosis; IWOS).

Juvenile Idiopathic Arthritis-Associated Anterior Uveitis

Anterior uveitis is the most common anatomic localization found in childhood uveitis and is associated with JIA in approximately 80% of the cases. Development of uveitis is most common among patients with oligoarticular, rheumatoid factor-negative and psoriatic arthritis subtypes. Antinuclear antibodies (ANAs) are positive in 90% of the patients. Clinical features of JIA-associated uveitis include mostly bilateral non-granulomatous inflammation, anterior in location, insidious at onset with chronic course. Juvenile idiopathic arthritis-associated AU is frequently initially asymptomatic. Uveitis in JIA can worsen over time as a result of many sight-threatening complications, such as band keratopathy in the visual axis, posterior synechiae, cataract, secondary glaucoma, macular edema, hypotony, epiretinal membrane, and optic nerve edema. Different studies have pointed out that several factors are associated with poor prognosis, including young age at onset, male gender, short interval between diagnosis of arthritis and uveitis, severity of uveitis at onset and ANA positivity. Unilateral permanent visual loss at the age of 18 was observed in 33% of the patients and bilateral visual loss occurred in 4%. Although uveitis in JIA is considered a disease of childhood, the majority of the patients experience persistent ocular inflammation into adulthood.

Tubulointerstitial Nephritis and Uveitis Syndrome

Tubulointerstitial nephritis and uveitis (TINU) syndrome affects mostly young patients with a peak incidence at the age of 14 years. It accounts for 1%–2% of all uveitis patients in specialized centers, but this number is probably underestimated since the nephritis component is often self-limiting and therefore not recognized. Uveitis in TINU syndrome has mostly a chronic bilateral course and is frequently classified as AU in the literature, however vitritis may be prominent. Definitive diagnosis of TINU syndrome is based on histopathological examination of renal tissue. However, renal biopsy is not being performed in mild cases, because of the associated risks. Probable TINU syndrome can be diagnosed by abnormal renal function urine analysis and systemic illness in the presence of uveitis. The combination of urinary β-2 microglobulin and serum creatinine is a relatively simple screening tool for renal dysfunction in order to diagnose probable TINU syndrome in young patients with uveitis.

Toxic Uveitis

Past and current medication history may reveal an association of AU with the development of inflammatory or toxic reactions to diverse medications used by various routes. Topical prostaglandin analogues may cause an acute non-granulomatous or chronic granulomatous AU. Topical brimonidine has been associated with a chronic AU, characterized by diffusely distributed stellate or micro-granulomatous KPs and a mild anterior chamber reaction, with or without concurrent conjunctivitis. Intravitreal triamcinolone acetonide or anti-vascular endothelial growth factor (VEGF) injections may cause a mild AU or a sterile endophthalmitis with hypopyon in more severe cases. An acute bilateral hypopyon may develop in immunocompromised patients who receive rifabutin as prophylaxis against Mycobacterium avium complex. Biphosphonates

FIGURE 1. Conjunctival and perilimbal redness with fibrinous reaction seen in the pupil and hypopyon in patient with HLA-B27-associated AU

that are used for the treatment of osteoporosis may cause an acute bilateral nongranulomatous AU with or without scleritis. Intravenous or intravitreal administration of cidofovir, an antiviral agent used for the treatment of CMV retinitis, may cause nongranulomatous AU typically associated with ocular hypotony. Bacillus Calmette–Guérin (BCG) vaccination or intravesical BCG for the treatment of bladder cancer may rarely cause an acute bilateral non-granulomatous or granulomatous AU. Melanoma or metastatic cancer patients receiving immune checkpoint inhibitors, such as ipilimumab, pembrolizumab, or nivolumab, may present with red eyes and mild or severe AU with posterior synechiae which may also be associated with keratitis. Anti-tumor necrosis factor (TNF) agents, particularly etanercept, may cause a paradoxical intraocular inflammation, which may sometimes present as a sarcoid-like granulomatous anterior uveitis. Bilateral acute iris transillumination (BAIT) syndrome, which can mimic acute iridocyclitis, has been linked to oral fluoroquinolones, especially moxifloxacin. It is characterized by severe photophobia associated with bilateral pigment dispersion into the anterior chamber, diffuse iris transillumination, and atonic distorted pupils.

**CLINICAL FEATURES OF COMMON BACTERIAL ANTERIOR UVEITIS ENTITIES**

**Syphilis-Associated Anterior Uveitis**

Non-granulomatous as well as granulomatous inflammation with iris nodules and posterior synechiae may be the initial presentations of syphilis. Roseola located on the iris represent a known feature in syphilis. Episcleritis, scleritis, keratitis, and hypopyon were also reported. Increase in IOP can occur during active inflammation. The diagnosis is usually based on serological tests. The Centers for Disease Control and Prevention currently recommends Enzyme Immunosassays (EIAs) and Chemiluminescent Immunoassays (CIAs) to detect antibodies to treponemal antigens as the best screening tests for syphilis followed by testing of positive specimens with the non-treponemal test, rapid plasma regain (RPR). Specimens positive by EIA and CIA and negative on RPR are submitted for a confirmatory Treponema pallidum particle agglutination test and if positive, the diagnosis of syphilis is confirmed.

**Tuberculosis-Associated Anterior Uveitis**

Intraocular inflammation secondary to tuberculosis (TB) is common in developing countries. Patients with AU due to TB present with unilateral or bilateral symptoms of redness, pain, photophobia, and floaters. Tuberculosis-associated AU can be markedly asymmetric. Adjacent ocular involvement in the form of scleritis, interstitial keratitis, phlycten and chronic conjunctivitis may also be seen. Anterior uveitis is characterized by medium to large KP's Figure 5, which can be few or diffuse over the corneal endothelium. Pigmented hypopyon has also been reported in intraocular TB. Fibrin in anterior chamber may be seen in aggressive inflammation. Inflammation may also be accompanied by Koepppe or Busaca nodules, or by nodules located in the iridocorneal
angle Figure 5, which may lead to secondary glaucoma. Broad-based posterior synechiae may also be seen Figure 5. Long standing chronic anterior uveitis may be associated with formation of pupillary membranes and iris neovascularization. Anterior uveitis may be accompanied by posterior segment involvement like choroiditis, retinal vasculitis, choroidal tuberculomas, optic nerve granulomas, and intermediate uveitis. Cataract and glaucoma are known complications seen in chronic AU. Confirmation of ocular TB is usually based on indirect evidence (diagnosis of systemic TB and/or good therapeutic response to anti-tuberculous therapy) and tests based on direct examinations of ocular tissues are less common. Molecular techniques performed on the intraocular fluids are becoming more widespread, but their clinical relevance is not yet clearly established.

**CLINICAL FEATURES OF COMMON VIRAL ANTERIOR UVEITIS ENTITIES**

**Herpes Simplex Virus and Varicella Zoster Virus-Associated Anterior Uveitis**

Herpes simplex virus and VZV, just as CMV belong to the Herpesviridae family. Following primary infection, life-long latency is a characteristic feature of this virus family. These viruses may present with AU, keratitis, dermatitis and/or conjunctivitis.

Common features of AU due to HSV or VZV infection are the unilateral localization and acute course commonly associated with subsequent recurrences or development of chronicity. Anterior chamber inflammation may be severe, and KPs of diverse types and sizes have been reported. An irregular pupil is a typical finding and is caused by iris atrophy (typically sectoral in HSV or more diffuse in VZV), which is caused by ischemic necrosis of iris stroma. Intraocular pressure is usually elevated during the acute stage and subsequent development of glaucoma is common.

Associated corneal opacities in herpetic AU are commonly observed, but corneal involvement may be entirely absent. Herpes simplex virus-associated keratitis typically shows stromal inflammation with associated endotheliitis and fine corneal dendrites without elevated appearance, while VZV-associated keratitis is interstitial with corneal ring infiltrates and rough dendrites lacking terminal bulbs that can have an elevated appearance. Furthermore, patients with HSV or VZV-associated AU show decreased corneal sensation. In contrast to HSV, VZV may show involvement of the vitreous. HSV usually affects children and young adults, VZV is more often...
seen in elderly and immunocompromised patients. Primary infection with HSV is characterized by typical skin or mucosa lesions. Varicella zoster virus gives a skin rash with associated vesicles, preceded by pain, in the ipsilateral dermatome. In cases associated with uveitis, typically the tip of the nose is also affected (Hutchinson sign).

**Cytomegalovirus-Associated Anterior Uveitis**

Cytomegalovirus-associated anterior segment inflammation in non-human immunodeficiency virus (HIV)-infected patients has a spectrum of clinical presentations, including Posner–Schlossmann and Fuchs uveitis syndromes (FUS). Cytomegalovirus-associated AU may also present as corneal endothelitis, with corneal edema ranging from a small localized area to diffuse bullous keratopathy, associated with mild AU. The IOP is often acutely or chronically elevated. Keratic precipitates may be non-granulomatous, granulomatous or stellate, and are usually located in the inferior half of the cornea. They may be diffuse, linear or show a ring pattern or may appear as a coin-like lesions. White, medium-sized, nodular lesions surrounded by a translucent halo are also possible. Vitritis or retinitis in these eyes is rare.35,36

**Rubella Virus-Associated Anterior Uveitis**

Rubella virus-associated AU was reported as one of the causes of FUS.5,37,38 However, RV-associated AU does not always fulfill the criteria of FUS. Patients with RV-associated AU are usually young adults at time of first ophthalmological presentation, and at that time typically have mild uveitis without synchiae, but may already have a cataract causing visual impairment. Unilateral involvement, the presence of fine KPs and diffuse iris atrophy are typical for RV-associated AU.39 Multiple iris nodules, easily visible in brown eyes, might be overlooked in patients with a light iris. The absence of redness and pain are typical. Focal “toxoplasmosis-like” chorioretinal scars may be seen.34 The presence of vitritis is frequent, and RV-associated AU may be mistaken for idiopathic intermediate uveitis.

**Human T-Cell Lymphotropic Virus Type 1-Associated Anterior Uveitis**

Southern Japan and Africa are the endemic areas for human T-cell lymphotropic virus type 1 (HTLV-1) infection. Major ocular symptoms of HTLV-1-associated uveitis are sudden onset of floaters and blurred vision, but pain, itching, and foreign body sensation may also be reported.40–42 On examination, typically uni- or bilateral mild iritis is seen, frequently associated with vitritis. Retinal vasculitis may also be seen.40–42 Graves’ disease is probably a risk factor for HTLV-1 associated uveitis and HTLV-1 associated uveitis appears to be related to HTLV-1 induced myelopathy, however these relationships require further investigation.42,43 In short, HTLV-1 associated uveitis is most frequently of intermediate type.

**Human Immunodeficiency Virus-Associated Anterior Uveitis**

Human immunodeficiency virus (HIV) causes a multi-system disease that may also involve the eyes. The presence of intraocular HIV-1 RNA was shown in about one-third of HIV-positive patients with infectious uveitis, but the HIV loads in the eye were typically lower than in plasma.44 Human immunodeficiency virus-induced uveitis was reported in patients in whom HIV loads in intraocular fluids exceeded the plasma loads; these patients are typically highly active, anti-retroviral therapy (HAART)-naïve and have low CD4 counts.45,46 Patients with HIV-associated uveitis complain of decreased vision but pain or conjunctival hyperemia is characteristically absent. The anatomic location of uveitis is typically anterior associated with vitritis and resembles FUS, but is more frequently bilateral. There are no associated retinal lesions or scars, no findings suggestive of opportunistic infections, and patients do not respond to topical corticosteroid therapy. Anterior segment inflammation is mild; KPs are small and/or medium sized, and scattered on the whole corneal endothelium. After the administration of HAART, the intraocular inflammation disappears quickly, as the intraocular and plasma HIV loads decrease. Therefore, HIV-induced uveitis should be suspected in non-treated HIV-positive patients or in those in whom such treatment has failed or in HIV-positive patients who have AU without any retinal lesions, no proven infectious cause and exhibit no response to topical corticosteroids.47

**Chikungunya Virus-Associated Anterior Uveitis**

Non-granulomatous AU may occur after a recent history of systemic chikungunya virus infection. Fine- to medium-sized KPs with pigmentation may be seen distributed all over the endothelium. The IOP may be increased at the time of active inflammation. A FUS pattern may also be seen in chikungunya virus-related AU.46 Accompanying posterior segment involvement in the form of retinitis is seen in many cases. Confirmation is by polymerase chain reaction (PCR) for chikungunya viral RNA. Treatment is usually with anti-inflammatory agents, like non-steroidal anti-inflammatory drugs (NSAIDS) and topical corticosteroids.48–50
Zika Virus-Associated Anterior Uveitis

Zika virus disease is a mosquito-borne infection transmitted by the *Aedes aegypti* mosquito. There are also reports describing infection following sexual, perinatal, and blood transfusions. The Zika virus infection was first reported in Uganda, clinically showing a similar presentation to Dengue virus. The disease is mild in adults with acute infection, and includes anterior uveitis with non-purulent conjunctivitis. It has a benign prognosis and is treated with topical steroids. In congenital infections, microcephaly is commonly described, and ocular findings include anterior segment abnormalities, such as iris coloboma and lens subluxation.

Ebola Virus-Associated Anterior Uveitis

Survivors of Ebola virus infection in convalescent phase suffer a slow and painful recovery with development of many complications. Around 20% of survivors of Ebola virus infection develop uveitis (after recovery of systemic disease), suggesting that the virus remains viable in the eye. It remains unclear whether Ebola-associated AU is caused by cytopathic effect of the virus or represents an immune response, but one-study reports on the detection of Ebola virus in aqueous humor of a patient with uveitis after the clearance of viremia. Anterior uveitis has been reported, which usually presents with KPs and posterior synechiae. Cataract and ocular hypertension may also occur in Ebola-associated AU. Approximately 40% of eyes become blind according to the World Health Organization classification. There are no known demographic and physical risk factors for the development of uveitis in Ebola virus infection survivors, with the exception of higher viral blood load. Interestingly, optic neuropathy without uveitis was also reported.

Uncertain Viral Anterior Uveitis Entities

*Epstein–Barr virus-associated anterior uveitis*

Epstein–Barr-virus (EBV) is also a member of the herpes virus family. It has repeatedly been reported as a cause of diverse types of uveitis, but the role of EBV in uveitis is not entirely clear, since PCR in aqueous fluid can be positive in EBV-infected patients without uveitis. Evidence of intraocular EBV antibody synthesis in AU is scarce. However, antiviral treatment with valgancyclovir of presumed EBV uveitis has been reported to be beneficial in patients presenting with uveitis and positive EBV serology. Epstein–Barr-virus-associated AU can be preceded by a flu-like prodrome and manifest as severe AU with fibrinous exudate in the acute stage, associated also with hyperemia and edema of the optic disc.

*Parvovirus-associated anterior uveitis*

Acute parvovirus B19 infection causes erythema infectious or fifth disease in children, sometimes with polyarthritis. Interestingly, after acute infection, serum autoantibodies may be measured in these patients, such as ANAs and rheumatoid factor. This similarity to JIA, in which patients may also have arthritis accompanied by ANA formation, raises the suspicion of a link between parvovirus B19 and JIA. Specific intraocular antibody production has been reported in patients with JIA-associated uveitis. There is little evidence that parvovirus B19 is a direct cause of uveitis, however; in rare instances, parvovirus B19-associated uveitis has been reported. Parvovirus B19 DNA was detected in aqueous humor of occasional patients with uveitis, but was also found in patients with cataract and serous retinal detachment.

**CLINICAL SYNDROMES IN ANTERIOR UVEITIS**

**Fuchs Uveitis Syndrome and Posner–Schlossman Syndrome**

Fuchs uveitis syndrome, which was first described in the medical literature almost 200 years ago, presents a clinical picture of unilateral chronic AU; although variations are described, typical features include small “stellite” KPs diffusely distributed across the corneal endothelium, low-grade anterior chamber cell and flare, absence of posterior synechiae, iris atrophy that ultimately results in the appearance of iris heterochromia, anterior vitreous cells, and secondary cataract and glaucoma. Recently confocal scanning laser ophthalmoscopy has expanded on these features, including identification of dendritiform and stippled KPs by standard scanning, and of abnormalities in iris autofluorescence by near-infrared scanning. Posner–Schlossman syndrome, or glaucomatocyclitic crisis, also was first recognized by ophthalmologists many generations ago, as a unilateral acute recurrent AU with few KPs, low-grade anterior chamber cells and flare, and markedly elevated IOP. More recent descriptions have highlighted the potential for progressive glaucomatous optic disc and visual field changes. Almost simultaneously, infectious causes now have been assigned to both FUS and Posner–Schlossman syndrome. Rubella virus has been recognized as a cause of FUS, with epidemiological evidence from the United States showing a decline in incidence since the introduction of the rubella vaccination and an increase in the percentage of cases in foreign-born residents, and detection of RV in aqueous humor by...
GWC measurement and/or PCR.\textsuperscript{5,38,39} Separately, PCR analyses in aqueous humor have identified CMV in patients previously diagnosed with Posner–Schlossman syndrome or FUS.\textsuperscript{36} It is likely that other viruses may cause clinical pictures that suggest one of these syndromes, as exemplified by the report from India, of a patient with bilateral FUS, whose aqueous fluid tested positively for Chikungunya viral, but not RV, DNA by PCR.\textsuperscript{48} Although it should be noted that concomitant involvement of RV could not be excluded as GWC, which has a sensitivity of nearly 100%, compared to 10%–20% for PCR, was not performed.

Immune Recovery Uveitis

Immune recovery uveitis (IRU) may present as an isolated anterior uveitis or more commonly with concurrent vitritis and CME, following immune recovery after highly active antiretroviral therapy in HIV patients or after tapering or discontinuation of immunosuppressive therapy in non-HIV patients with CMV retinitis. The condition represents an active immune response to CMV antigens that persist in the eye.\textsuperscript{78–80} Posterior synechiae and posterior subcapsular cataract may develop, and after intraocular surgery, the postoperative course may be complicated by large inflammatory deposits on the surface of the intraocular lens.\textsuperscript{75}

LABORATORY DIAGNOSIS OF VIRAL UVEITIS

For the laboratory diagnosis of viral AU, one may perform blood analysis. However, serology at the most excludes a certain virus in the case of a negative result, or indicates whether a patient has ever been infected with the particular virus in the case of a positive result. In addition, most causes of viral AU have high seroprevalences in most parts of the world, particularly VZV and RV, rendering serology for these causes of little value. Polymerase chain reaction on peripheral blood is by no means conclusive, as negative results do not exclude an intraocular infection, and positive results do not prove one. A definitive diagnosis is only obtained by intraocular fluid analysis. Aqueous humor may be investigated by PCR or GWC analysis, to determine intraocular antibody production.\textsuperscript{57,38,81}

Depending on the immune status, time of sampling and type of uveitis (chronic or subacute), PCR or GWC analysis may be more sensitive. However, as these data may not always be available, it is advisable to perform both assays if possible.\textsuperscript{82,83}

CONCLUSIONS

Viral AU is typified by unilateral mild AU with fine- or medium-sized KPs, some form of iris atrophy, and sometimes high IOP, see Table 2. Cataract and glaucoma are common complications in viral AU and presence of vitritis in specific viral entities is common. There is an overlap in the clinical manifestations of AU caused by viruses and other non-viral forms of AU. Moreover, there is no specific feature that is indicative of viral AU, as many signs and symptoms may vary between specific viral causes (pain, redness, synechiae, corneal, and vitreous involvement).

Several viral AU entities may be accompanied by a prominent vitritis (eg. RV, HTLV, and HIV), which can be misleading in making of correct diagnosis. FUS is usually also classified as AU, however vitreous involvement in FUS may be severe, and associated chorioretinal scars and papillitis also have been reported. It might be more correct to classify patients according to their actual presentations as intermediate or panuveitis.

In conclusion, a viral cause of AU should be suspected in patients with unilateral AU, exhibiting small- or medium-sized KPs, some form of iris atrophy, high IOP, and early development of a cataract. Whilst medical history, serologic results and clinical features might raise a suspicion of viral etiology, the definitive diagnosis can be proven by aqueous humor analysis.
