“The quest of the B cell”

Developing B cells have a long way to go before they are ready to encounter disease-causing pathogens. In order to make it a successful journey, multiple factors are required, without which the quest will fail. The ultimate dream of the B cell is to fight a pathogen and become an antigen-experienced B cell that can generate a fast and strong immune response, which contributes to antigen-specific immunity.

B-cell Development and Primary Antibody Deficiencies

B-celontwikkeling en primaire antistofdeficiënties

PROEFSCHRIFT

ter verkrijging van de graad van doctor
aan de Erasmus Universiteit Rotterdam
op gezag van de rector magnificus
Prof.dr. S.W.J. Lamberts
en volgens besluit van het College voor Promoties.
De openbare verdediging zal plaatsvinden op
woensdag 20 juni 2007 om 13.45 uur

door

Menno Cornelis van Zelm

geboren te Utrecht

PROMOTIECOMMISSIE

Promotoren: Prof.dr. J.J.M. van Dongen
Prof.dr. R. de Groot

Overige leden: Prof.dr. H. Hooijkaas
Prof.dr. C. Murre
Prof.dr. C.J.M. van Noesel

Copromotor: Dr. M. van der Burg

The studies described in this thesis were performed at the Department of Immunology, Erasmus MC, Rotterdam, the Netherlands and partly at the division of Biological Sciences, University of California San Diego, La Jolla, CA, USA.

The studies were financially supported by 'Sophia Kinderziekenhuis Fonds' (SKF; grant 349), and partly by Ter Meulen Fund - Royal Netherlands Academy of Arts and Sciences (KNAW), Trustfonds - Erasmus University Rotterdam and the Dutch Society for Immunology (NVvI).

The printing of the thesis was supported by Erasmus University Rotterdam, J.E. Jurriaanse Stichting, Stichting Kind & Afweer, Baxter B.V., Dr. Ir. Van de Laar Stichting, Beckman Coulter Nederland B.V. and BD Biosciences.

General Introduction

The immune system of higher vertebrates, such as humans, is a complex interplay of cells and protein products that protects the body from invading micro-organisms. The first line of defense is formed by the skin and mucous membranes. The second line consists of proteins (e.g. complement) and immune cells (e.g. macrophages, granulocytes, natural killer (NK) cells) that are part of the innate immune system. T and B lymphocytes are part of the specific adaptive immune system: the third line of defense. These lymphocytes adapt their response during an infection to improve recognition of the pathogen and this improved response is then retained after the pathogen has been eliminated in the form of an immunological memory. Classically, the cells of the innate immune system were thought to react a-specifically, whereas the adaptive immune cells carried out a specific immune response. However, more recently innate immune cells were found to carry evolutionarily conserved receptors, named Toll-like receptors (TLRs). These receptors play a crucial role in early host defense against invading pathogens and are specific enough to discriminate self and pathogens.

B lymphocytes contribute to the immune system by production of antigen-specific antibodies (immunoglobulins; Ig). The antibody response to a pathogen is the classical example to demonstrate the enormous capacity and specificity of the adaptive immune response (Figure 1). Similar to most immune cells, B lymphocytes are generated throughout life from hematopoietic stem cells in bone marrow (Figure 2). Every newly generated B-lymphocyte carries a specific Ig receptor, which has been generated during differentiation in bone marrow

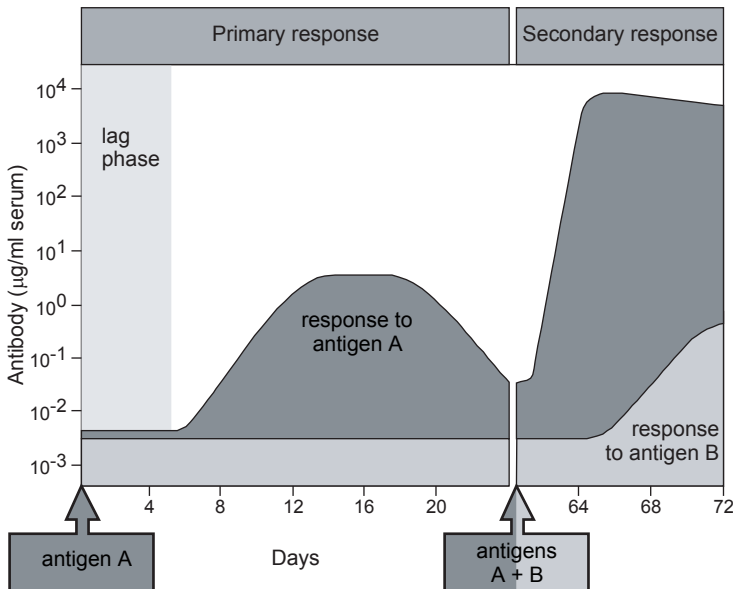

Figure 1. The course of a typical immune response.

Upon first encounter with antigen A, an immune response is initiated and antibodies against antigen A are produced after a lag phase of several days. The antibody levels reach a plateau and then decrease. When the animal is later challenged with antigen A, a very rapid and intense response occurs. The response to antigen B at the same time of the booster with antigen A, resembles the initial and primary response to antigen A. This illustrates the antigen-specific build up of memory. Figure adapted from Janeway *et al.* Immunobiology, 2001, Garland Science.

Figure 2. Scheme of B-cell differentiation.

B cells develop from hematopoietic stem cells through various precursor stages in bone marrow. In the periphery, naive mature B lymphocytes can respond in absence of T-cell help to antigen in the marginal zone, or they undergo a more powerful T-cell dependent response in the germinal center reaction. Eventually, Ig-secreting plasma cells and long-lived memory B cells are formed.

by somatic rearrangement of the gene complexes encoding the Ig heavy chain (IgH) and Ig light chain (Ig κ or Ig λ) molecules. When it recognizes an antigen with its specific Ig receptor, the B-lymphocyte undergoes clonal expansion to generate daughter cells that differentiate into either memory B cells or plasma cells, which produce and excrete soluble Ig molecules. As shown in Figure 1, this primary response takes a couple of days and solely targets one specific pathogen. Another property of the specific immune system is the build-up of memory. When the same pathogen is encountered for the second time, the immune system will respond quicker and more powerful, both with respect to the number and the affinity of the antibodies. However, when a different pathogen is encountered that has not been ‘seen’ before, a primary response will be initiated.

Generation of a large repertoire of B lymphocytes and the response of one of these B lymphocytes to antigen is a multi-step process. Multiple proteins are critical for proper B-cell differentiation in bone marrow and the B-cell antigen response. The lack of one of these proteins leads to a problem with the humoral immunity of the individual, which is seen in patients with primary antibody deficiency diseases. These children or young adults carry rare inherited disorders and are subject to multiple, recurrent (mainly) bacterial infections.

This thesis focuses on the process of B-cell differentiation and the defects that lead to primary antibody deficiency diseases.

1. HUMAN B-CELL DIFFERENTIATION

B-cell commitment

Hematopoietic stem cells (HSC) in bone marrow are long-lived and self-renewing. They generate multilineage progenitor cells (MLP) that are capable of developing into erythroid, myeloid and lymphoid cells (Figure 3). While they are capable of developing into each of these cell types, every single MLP will only develop into one specific cell type.

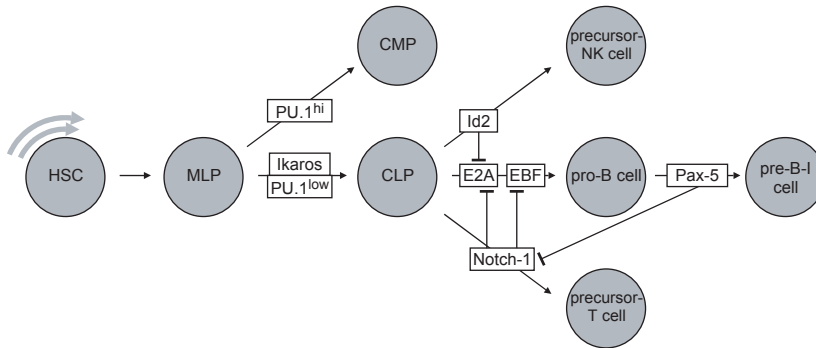

Figure 3. Schematic overview of differentiation and commitment from hematopoietic stem cells (HSC) to the B-cell lineage.

Multilineage progenitor cells (MLPs) derive from HSC and subsequently depend on Ikaros and low PU.1 expression to develop into common lymphoid progenitors (CLPs). The transcription factors E2A and EBF support further differentiation into pro-B cells, whereas their expression is inhibited in precursor-NK and precursor-T cells by Id2 and Notch1, respectively. Pax5 ensures commitment to the B-cell lineage. Figure adapted from Busslinger.⁵

This progressive restriction in developmental potential is thought to occur in intermediate steps.¹ Due to the low numbers of early progenitor cells and the fact that they are located in bone marrow, limited data is available from B-cell commitment in man. In contrast, many studies have been performed in mice. Therefore, mainly data obtained from mouse models will be discussed in this paragraph.

The MLPs generate populations restricted to either lymphoid (common lymphoid progenitor; CLP) or erythroid/myeloid (common myeloid progenitor; CMP) cell lineages (Figure 3).^{2, 3} CMPs can develop into erythrocytes and myeloid cells, e.g. monocytes and granulocytes. CLPs give rise to natural killer (NK) cells, T cells and B cells. Commitment to the B-cell lineage takes place in several consecutive steps. B-lineage specification occurs already at the MLP/CLP stage.⁴ Although B-cell fate is already induced early, the progenitor cell keeps a high degree of lineage plasticity. The myeloid potential is not lost until the pro-B-cell stage, and B/T lineage plasticity persists until the pre-B-I cell stage.⁴ From this stage onwards the cell is fully committed to the B-cell lineage (Figure 4).

Multiple proteins, particularly transcription factors, are involved in controlling cell fate decisions in HSC, MLP, CMP and CLP (reviewed in refs 5, 6). Ikaros and PU.1 act in parallel pathways to control the development of CLP from MLP.^{7, 8} This is done in part by regulating the expression of essential signaling receptors (Flt3, c-Kit, and IL-7R α).^{8, 9}

The generation of pro-B cells depends on transcription factors encoded by the *E2A* and *EBF* genes. The *E2A* gene encodes the two splice variants E12 and E47, which belong to the basic helix-loop-helix (bHLH) family of transcription factors.^{10, 11} Together with E2-2 and HEB, these proteins belong to class 1 bHLH proteins, also called E-proteins. E12 and E47 are widely expressed and bind specific DNA sequences, E-boxes, as homo- or heterodimers with other E-proteins. In developing B cells, mainly E47 homodimers are detected. It is currently

Figure 4. Scheme of human precursor-B-cell differentiation.

Precursor-B cells differentiate through five functionally distinct stages in bone marrow during which they rearrange their Ig genes before they migrate to the periphery with a functional BCR. The distinct stages can be identified by membrane and cytoplasmic expression patterns of several proteins.

unclear what factors regulate E47 expression and homodimerization in pro-B cells; the latter is probably controlled by hypophosphorylation of N-terminal serine residues.¹²

Within the hematopoietic system, EBF is exclusively expressed in the B-cell lineage and binds as homodimer to conserved palindromic DNA sequences.¹³⁻¹⁵ E2A proteins and PU.1 are important regulators of EBF expression.^{16, 17} E47 and EBF coordinately regulate the expression of multiple genes required for proper B-cell differentiation, including components of the pre-BCR and the transcription factor Pax-5.¹⁸ EBF and Pax-5 initiate a B-cell specific transcription program and suppress the expression of genes required for development of other hematopoietic lineages (e.g. Notch1, Flt3), thereby committing the pro-B cell to the B-cell lineage.¹⁹⁻²² Analogously, regulating factors of other lymphoid lineages, such as Notch1 in early T-cell progenitors and Id2 in precursor-NK cells, can suppress the genes that regulate early B-cell differentiation (Figure 3).

IGH gene rearrangements

The primary objective of every precursor-B cell in bone marrow is to generate a unique B-cell antigen receptor (BCR). In doing so, every mature B-lymphocyte in peripheral lymphoid organs contributes to the enormous antigen-recognition repertoire, which is estimated to be over 10¹². In order to generate a specific antigen receptor, every precursor-B cell initiates V(D)J recombination on the Ig receptor encoding loci (*IGH*, *IGK* and *IGL*). In contrast to other genes, these loci lack a functional first coding exon. Instead they carry multiple variable

Figure 5. Schematic representation of *IGH* gene rearrangement.

A. First, a D_H gene segment is joined to a J_H gene segment. Subsequently, a V_H gene segment is coupled to the DJ_H joint. The VDJ exon is transcribed and spliced to the C_μ exons. **B, C.** A functional in-frame $Ig\mu$ protein will be transported to the plasma membrane with anchoring molecules CD79a and CD79b, and surrogate light chain molecules λ 14.1 and VpreB (pre-BCR in large pre-B-II cells), or a functional Ig light chain protein (BCR in immature and mature B cells).

(V), diversity (D) and joining (J) gene segments (Figure 5). A functional first exon is formed by genomic coupling of one V, one D and one J gene segment.²³ Because *IGK* and *IGL* lack D gene segments, direct V–J gene rearrangement is initiated on these loci.

The first Ig gene rearrangements that occur during precursor-B-cell differentiation are D_H – J_H rearrangements.^{24, 25} These rearrangements are initiated on both *IGH* alleles.^{26, 27} In mouse models, D_H – J_H rearrangements are already detectable in some CLP, but the majority is initiated in pro-B cells.⁴ Although CLP have the potential to differentiate into multiple cell lineages, D_H – J_H rearrangements are fairly specific for B lymphocytes: only low levels of D_H – J_H have been found in T cells, NK cells and myeloid cells. Furthermore, no V_H – D_H , Ig light chain or TCR gene rearrangements are induced in CLPs and pro-B cells indicating that additional factors specifically target the common V(D)J recombinase machinery to D_H and J_H gene segments. The transcription factors E2A and EBF appear to have an important role in making the *IGH* loci accessible for D_H – J_H recombination. This is mediated in part by the intron enhancer (iE μ) downstream of the J_H gene segments, which consists of several conserved motifs, among which are five E-boxes.

Complete V_H – D_H rearrangements are initiated in pre-B-I cells (Figure 4). Initially, one allele is poised to rearrange and the other allele only rearranges when rearrangement of the first allele was not successful. Because V and J gene segments have one reading frame and stop codons can be introduced in the coding joint, less than one-third of the rearrangements can generate functional proteins. V_H – D_H rearrangements are highly B-cell specific and are not present in other cell lineages. Murine studies have indicated prominent roles for the Pax5 transcription factor in making the V_H gene segment region accessible to the RAG proteins. Furthermore, signaling via the IL-7R and downstream transcription factor Stat5 was found to be crucial for initiation of V_H – D_H rearrangements in mouse models.

Prior to V(D)J recombination, two gene segments have to be spatially co-localized. Since the Ig loci can be over 1 Mb in size, gene segments poised to rearrange can be located in genomically distant locations. Recent studies in mouse models aimed to visualize the spatial co-localization of gene segments in the *IGH* locus in cells poised to rearrange.^{28, 29} Using 3D fluorescence *in situ* hybridization techniques, the *IGH* locus was shown to undergo large-scale compaction and looping of distant regions. These processes are independent of RAG-2 and are probably mediated by transcription factor activity.²⁹ The nature of the compaction and looping as well as the DNA motifs mediating these processes are topics for further research.

Molecular mechanisms of V(D)J recombination

V(D)J recombination is a highly specific process that is only initiated in precursor-B and precursor-T cells in order to generate antigen receptors. During Ig gene rearrangements, double stranded DNA breaks are induced. These breaks are unwanted in other genes, thus requiring very specific targeting of the Ig loci.

The double stranded DNA breaks are induced by a heterodimer composed of the recombinase activating gene protein products RAG-1 and RAG-2 (Figure 6). This RAG-1/RAG-2 dimer specifically recognizes a DNA sequence, the recombination signal sequence (RSS), composed of conserved heptamer and nonamer sequences. These conserved sequences are separated by either a 12-bp or a 23-bp DNA sequence (spacer). All Ig gene segments are flanked by an RSS, and rearrangements commonly occur between gene segments of which

one is flanked by a 12-bp RSS and the other by a 23-bp RSS.³⁰ This is known as the 12-23 rule. The RAG-dimers juxtapose the two gene segments poised to rearrange and nick the DNA of both at the border of the gene segment and flanking RSS.³¹⁻³³ The 3'OH at each nick attacks the antiparallel strand to create a DNA hairpin at the gene segment. Blunt ends remain on the RSS sequences and are directly joined by non-homologous end joining (NHEJ) to create a circular excision product. The hairpins on the coding end are processed prior to ligation by NHEJ components.³⁴ The proteins Ku70 and Ku80 first bind the coding ends and recruit the

Figure 6. Schematic overview of V(D)J recombination.

The RAG proteins cleave two gene segments at the border of the RSSs. This results in two hairpinned coding end and two blunt signal ends. The blunt signal ends are directly joined by a complex of Ku70, Ku80 and DNA-PKcs. These proteins also bind the two coding ends before Artemis cleaves the hairpins. Subsequently, the coding ends are processed by endonuclease and TdT activity. Finally, a complex of DNA ligase IV, XRCC4 and Cernunnos is required to ligate the ends into a coding joint.

catalytic subunit of DNA-dependent protein kinase (DNA-PKcs) and Artemis.^{35,36} The protein Artemis nicks the hairpin preferentially at the tip or 1-2 bp 5' of the tip.^{37,38} When the nick is introduced 5' of the tip, this results in a 3' overhang. Complementary nucleotides can be inserted from the 5' end to generate a blunt end, resulting in the generation of palindromic (P-)nucleotides. Furthermore, exonuclease proteins can remove nucleotides, whereas the terminal deoxynucleotidyl transferase (TdT) protein can add random (N-)nucleotides.^{39,40} Finally, the Ku heterodimer recruits a protein complex, including XRCC4, DNA ligase IV and Cernunnos (XLF), that ligates the coding ends.⁴¹⁻⁴³ The processing of the coding ends before ligation results in a unique coding joint sequence.

Pre-B-cell receptor signaling

Once a VDJ_H exon is formed by Ig gene rearrangements, RNA transcripts are produced and the exon is spliced to the Ig μ encoding exons (Figure 5). If the resulting Ig μ heavy chain protein is functional and is able to pair with the surrogate light chain proteins λ 14.1 and VpreB, this pre-BCR complex is expressed on the plasma membrane of the cell with anchoring molecules CD79a and CD79b. Expression of a functional pre-BCR is an important checkpoint in precursor-B-cell differentiation.^{44,45} The receptor induces multiple processes via downstream signaling pathways (Figure 7). First, further rearrangement of the *IGH* alleles is

Figure 7. Schematic overview of factors and downstream processes regulated by pre-BCR signaling.

The pre-BCR and the IL-7R signal via Lyn, Syk, Stat5 and the Ras-Raf-MEK-ERK pathway for proliferation. Signaling of the pre-BCR via Syk is also required for allelic exclusion. Furthermore, the pre-BCR signals via BLNK and Btk to limit proliferation and induce Ig light chain rearrangements. Figure adapted from Hendriks and Middendorp.⁴⁴

inhibited by direct downregulation of the RAG proteins.⁴⁶ In addition, the *IGH* alleles are made inaccessible for V(D)J recombination. This process, which is called allelic exclusion, inhibits recombination on the second allele ensuring that only one functionally rearranged *IGH* allele is produced. Second, the cell will undergo several cycles of proliferation. Third, transcription of the genes encoding components of the surrogate light chain is inhibited.⁴⁷ As a result, the pre-BCR complex is quickly downregulated and proliferation will be limited. Finally, the cell will upregulate RAG protein levels and initiates Ig light chain gene rearrangements. This complete sequence of events is regulated by a complex network of downstream signaling events initiated upon cross-linking of pre-BCR complexes. It is still controversial whether cross-linking is induced by a ligand, or directly by interaction between the surrogate light chains of pre-BCR complexes.⁴⁸⁻⁵⁰ Upon cross-linking, the intracellular protein-tyrosine kinase Lyn phosphorylates immunoreceptor tyrosine-based activation motifs (ITAMs) in CD79a and CD79b. As illustrated in Figure 7, upon ITAM phosphorylation multiple signal transduction molecules are recruited to the pre-BCR complex.

The use of mouse models has contributed greatly in dissecting the pathways through which the pre-BCR signals for the above-mentioned four processes, which have been difficult to address due to the (partial) redundancy of some proteins. Lyn recruitment to the pre-BCR complex activates the Ras-Raf-MEK-ERK pathway to signal for proliferation.⁵¹ This pathway is thought to intersect with IL7R signaling, which also activates this pathway via Lyn.^{51,52} Allelic exclusion is established through signaling via Syk and signaling via PLC γ .^{53,54} BLNK and Btk have been shown to activate PLC γ , however, both proliferation and allelic exclusion were found to be established in absence of both BLNK and of Btk.⁵⁵⁻⁵⁷ Therefore, PLC γ could be activated through other mechanisms, e.g. via Ca²⁺ signaling, or homologs of BLNK and/or Btk are partially redundant for PLC γ activation. Termination of proliferation and initiation of Ig light chain rearrangements are dependent on signaling via BLNK and Btk. However, the mechanisms through which the surrogate light chain expression is inhibited and the *IGK* locus is made accessible are largely unknown.

Although human and mouse precursor-B-cell differentiation are very similar, observations show that several aspects of pre-BCR signaling may be different in humans. First, in contrast to mouse models, IL7R signaling is dispensable for human precursor-B-cell differentiation.^{58,59} Furthermore, Btk has been shown to be important for pre-BCR induced proliferation of human pre-B-II cells.⁶⁰

BCR selection in bone marrow

Signaling from the pre-BCR induces Ig light chain rearrangements. Similar to V_H-D_H rearrangements, the initiation of V-J rearrangements on the *IGK* and *IGL* light chain alleles appears to be highly regulated.⁶¹ First, one *IGK* allele is poised to rearrange. When this renders a non-functional rearrangement, the other *IGK* allele will be rearranged. *IGL* gene rearrangements will be induced when both *IGK* alleles are non-functional. These four Ig light chain alleles provide the cell for multiple options to produce a functional Ig light chain (Figure 8).

In addition, because only single step rearrangements are required to produce a functional VJ exon, multiple attempts are possible on a single allele. After a rearrangement renders a non-functional allele, an upstream V and a downstream J gene segment can rearrange, thereby

removing the pre-existing V–J rearrangement from the genome.

Once an Ig light chain protein is generated that can pair with the Ig heavy chain to form a functional BCR, the cell will be positively selected into the next differentiation stage (immature B cell). Immature B cells that carry an autoreactive BCR go into apoptosis (negative selection), induce additional Ig gene rearrangements, or become anergic. Before the B cell can create another Ig light chain protein, the allele that encodes the autoreactive protein has to be removed from the genome. In addition to subsequent V_{κ} – J_{κ} rearrangements, the *IGK* locus can initiate rearrangements between V_{κ} gene segments and the kappa-deleting element (Kde), which is located downstream of the C_{κ} exons (Figure 8).⁶² These rearrangements remove the rearrangement and the C_{κ} exons from the genome. The Kde element can also rearrange with an RSS sequence located upstream of the C_{κ} exons and downstream of the J_{κ} gene segments. This rearrangement removes the C_{κ} exons from the genome. Both types of *IGK*-deleting rearrangements are commonly found in mature B lymphocytes of healthy individuals.

Figure 8. Schematic overview of Ig light chain gene rearrangements.

IGK contains 76 functional V and five functional J gene segments that can be rearranged to form a functional VJ_{κ} exon. In addition, V_{κ} gene segments and an intron-RSS can rearrange with the kappa-deleting element (Kde). These kappa-deleting rearrangements remove the enhancer and the C_{κ} region, thereby making the allele non-functional. The *IGL* locus contains 56 functional V and three functional J-C clusters that are often used V_{λ} - J_{λ} rearrangements.

Naive B-lymphocyte homeostasis

Once a functional BCR is formed that does not display high affinity for autoantigens, the immature B cell will further mature and migrate via peripheral blood to peripheral lymphoid organs as a transitional B lymphocyte. In the periphery, the transitional B-lymphocyte will develop into a naive mature B lymphocyte. It is currently unclear which processes and factors are involved in this development. Transitional and naive mature B lymphocytes are functionally different: recent reports demonstrate that transitional B lymphocytes are immature in their migration capacity and response to antigen.^{63, 64} Naive mature B lymphocytes are thought to be short-lived unless they are activated upon antigen encounter.

The absolute number of B lymphocytes is tightly regulated. In principle, four processes can contribute to this homeostasis: 1, output from bone marrow; 2, survival; 3, loss of naive B lymphocytes via further maturation after antigen encounter;⁶⁵ and 4, antigen-independent (homeostatic) proliferation. Homeostatic proliferation without differentiation of naive mature B lymphocytes independent of antigen has been reported in mouse models in response to a B-cell deficit.⁶⁶⁻⁶⁸ However, it remains unclear to what extent proliferation contributes to naive B-lymphocyte numbers in healthy individuals.

T-cell dependent and T-cell independent B-cell responses to antigen

Naive mature B lymphocytes undergo an immune response upon recognition of antigen with their specific BCR. The response of a B cell to antigen depends greatly on the strength of the interaction and the presence of co-stimulatory signals. Upon antigen binding, the BCR complex translocates to glycolipid and cholesterol-rich membrane microdomains ('lipid rafts'). The B-cell co-receptor complex, consisting of CD19, CD21, CD81 and CD225 signals in conjunction with the BCR,⁶⁹ thereby reducing the threshold for antigen-dependent stimulation.^{70, 71} Since CD21 is a receptor for complement fragment C3d, C3d-loaded antigen can be bound by CD21 and the BCR, thus resulting in co-localization of the two complexes (Figure 9).

Figure 9. Schematic representation of antigen binding by the BCR and the CD19-complex.

The CD19-complex, consisting of CD19, CD21, CD81 and CD225, signals together with the BCR. C3d-bound antigen can be recognized by CD21, which is a complement receptor, thus bringing the BCR- and the CD19-complex together.

Most B-cell responses are mediated via cognate CD4⁺ T-cell help. These T cells are activated by exposure to dendritic cells (DC) presenting antigen-derived peptides, and subsequently express B-cell activating membrane-bound and soluble factors. Important membrane-bound receptors are CD40L and ICOS (inducible co-stimulator), which interact with respectively CD40 and ICOSL on the B cell. Upon T-B interaction, the activated B cells undergo extensive proliferation and somatic hypermutation (SHM) of their Ig genes in a highly organized structure in lymph nodes and other secondary lymphoid organs: the germinal center. In this anatomical site, an apical light and a basal dark zone can be identified. The dark zone mainly consists of proliferating B cells (centroblasts) in a network of follicular dendritic cells (FDC). These cells from stromal origin express molecules that are important for B cell proliferation and survival. In this respect, the FDCs are important for affinity maturation by selectively providing survival signals to B cells that bind antigen with high affinity. To this purpose, FDCs present antigen bound to C3d via CD21 on their plasma membrane. After proliferation and SHM, the centroblasts become resting centrocytes and undergo Ig class switch recombination (CSR) in the light zone of the germinal center. Subsequently, the germinal center-derived B lymphocytes differentiate into antibody-producing plasma cells or long-lived memory B cells.

The splenic marginal zone contains B lymphocytes that show a fast response to blood borne pathogens. The BCRs of these marginal zone B cells often recognize repetitive components. Consequently, multiple BCRs can bind to one antigen and are capped together thereby generating a strong signal. The strong signal resulting from this capping enables these cells to generate an immune response independently of T-cell help. Interestingly, these cells have been found to carry SHM on their Ig loci. Because they did not interact with T cells, this molecular process was potentially initiated via a different mechanism.⁷²

Molecular processes of somatic hypermutation and Ig class switch recombination

During the proliferation phase of a B-cell antigen response in the germinal center, the DNA encoding the variable regions of the Ig heavy and Ig light chain proteins is the target of SHM. These mutations can be induced throughout the variable regions, although mutations are preferentially found in the DGYW sequence motif (D denotes G, A or T; Y denotes C or T; W denotes A or T).⁷³ Modifications in the amino acid sequence of Ig molecules are unwanted in the domains that are important for structural organization of the molecule, i.e. framework (FR-)regions. In addition, mutations that negatively influence antigen binding in the antigen-recognition domains, the complementary-determining regions (CDR), are unfavorable. Consequently, the B cells that acquire these mutations go into apoptosis due to a lack of BCR-mediated proliferative signals. In contrast, mutations in CDRs that result in higher affinity interaction with antigen lead to a selective advantage for the cell to survive and proliferate. Consequently, SHM and selection greatly contribute to antigen-dependent affinity maturation.

In addition to V(D)J recombination and SHM, a third molecular mechanism is involved in the antibody response: CSR. The *IGH* locus contains multiple constant regions downstream of C μ . In precursor- and naive mature B lymphocytes, these regions are not used because the rearranged VDJ_H exon is spliced to the C μ exons. In the germinal center, the B cell is capable of rearranging the Ig switch region upstream of C μ with one of the switch regions upstream

of the other constant regions. This process results in deletion of the intervening DNA and places a different constant region directly downstream of the J_H region. CSR does not alter the antigen specificity or membrane expression of the receptor on the B cell. The constant region is important for mediating immune responses by secreted Ig after binding to antigen. Because the different isotypes are recognized by specific receptors on immune cells, they exhibit different effector functions.

Key player in the molecular processes of SHM and CSR in mature B lymphocytes is the activation-induced cytidine deaminase (AID). Although AID shares homology with RNA-editing enzymes, it is currently believed that AID deaminates cytidine (C) residues to uracil (U) in single stranded genomic DNA instead of RNA transcripts. AID probably acts during the DNA replication phase, when single strand formation of genomic DNA is temporarily induced. The enzymatic function of AID ultimately results in G•U mismatches that are repaired via different mechanisms for SHM and CSR.

The uracil residues induced by AID can either be replicated in a proliferating cell, resulting in a transition mutation (C to T, and G to A), or be removed by uracil-N-glycosylase (UNG) creating an abasic site (Figure 10).⁷⁴ This site can attract either members of the base excision repair (BER), or the mismatch repair (MMR) machinery. The BER machinery specifically targets the abasic site and error-prone DNA polymerases add a random nucleotide generating

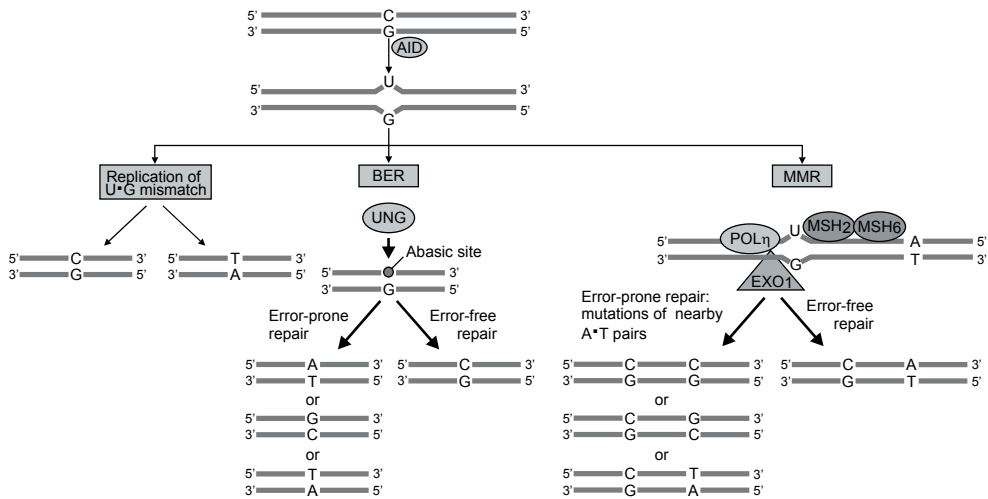

Figure 10. The error-prone repair of AID-induced lesions.

AID initiates SHM by the deamination of cytidine (C) nucleotides on single-stranded DNA. The resulting uracil (U)•guanine (G) mismatch can be repaired by one of three pathways. (1) For a mutation to be fixed at the site of deamination, error-free DNA repair must be 'perturbed' to become error-prone. If the mismatch is carried unrepaired to replication, DNA polymerases will insert an adenosine (A) opposite the U nucleotide, ultimately creating C to T, and G to A transition mutations. (2) In base-excision repair (BER), replication over an abasic site created by uracil-DNA glycosylase (UNG) will give rise to both transition and transversion mutations. (3) A U•G mismatch also recruits the mismatch repair (MMR) machinery, which is thought to create mutations at A•T base pairs near the initiating U•G lesion. EXO1, exonuclease 1; MSH, homologue of Escherichia coli MutS; POLη, polymerase (DNA directed)-η. Figure adapted from Odegard and Schatz.⁷⁴

transition and transversion mutations. Consequently, this process only generates mutations at G•C bases, which reflect direct targets of AID. *In vivo*, G•C bases constitute only half of the mutations generated, whereas the other half are A•T bases. These mutations are indirect targets and induced by patch repair of the MMR machinery. The G•U mismatches are recognized by a heterodimer of MutS homology proteins MSH2 and MSH6. This heterodimer recruits additional mismatch repair proteins, among which are MLH1, PMS2 and exonuclease 1 that excise the DNA strand containing the G•U mismatch. This strand is newly synthesized by error-prone translesional polymerase eta ($\text{pol}\eta$). The error-prone nature of this polymerase

Figure 11. Molecular processes of CSR.

The Ig switch regions (s) contain multiple hot-spots for AID targeting. Consequently, multiple single-stranded DNA lesions can occur in close proximity. These can result in double-stranded DNA breaks and when two Ig switch regions are brought into close proximity, they can be recombined. This results in a hybrid switch region and excision of the intervening DNA as a circular product. **A.** Co-localization of Ig switch versions, S μ and S γ 2. **B.** High density AID-induced lesions can result in double stranded DNA breaks and recombination between the Ig switch regions.

can result in the generation of mutations in A•T (and G•C) bases that were not original targets of AID.

The Ig switch regions (s) upstream of the constant gene regions consist of tandem repeats of 20-80 bp sequences, which contain numerous AID hotspot motifs (WRC/GYW). Similar to SHM, the U induced by AID can be removed by UNG and the strand excised by mismatch repair proteins. Because of the high density of hotspot motifs, two abasic sites can be induced within a small range on opposite strands (Figure 11). When both breaks result in excision of DNA strands, this will lead to a double stranded (ds)DNA break instead of just a single stranded break. Consequently, NHEJ proteins are recruited similar to V(D)J recombination. The induction of dsDNA breaks in S μ and one of the other switch regions will lead to rearrangement between the switch regions and excision of the intervening DNA.

Control of B-lymphocyte homeostasis and antigen responses by TNF family ligands BAFF and APRIL

B-cell activating factor (BAFF) and a proliferation-inducing ligand (APRIL) are two tumor necrosis factors (TNF) that are implicated in several aspects of B-cell survival and Ig isotype switching and production.^{75, 76} BAFF and APRIL can both bind the BCMA (B-cell maturation antigen) and TACI (transmembrane activator and CAML interactor) receptors,⁷⁷⁻⁸¹ whereas BAFF specifically binds to a third receptor: BAFF-R,^{82, 83} and APRIL can interact with proteoglycans (Figure 12).^{84, 85} Similar to other TNF receptors, BCMA, TACI and BAFF-R form homo-trimeric complexes on the plasma membrane. Both ligands are expressed on the plasma membrane and excreted as trimeric molecules by multiple cell types from both hematopoietic (myeloid cells) and non-hematopoietic origin (reviewed in ref. 86). In addition, 20 BAFF trimers can form a 60-mer virus-like structure.^{87, 88} Although BAFF and APRIL

Figure 12. Ligand specificity of BAFF and APRIL and function assignment of their receptors.

BAFF and APRIL can both bind TACI and BCMA, whereas BAFF specifically recognizes BAFF-R, and APRIL can specifically interact with proteoglycans. The receptors are differentially expressed during B-cell differentiation and signal for unique processes, as indicated. Figure adapted from Schneider.⁹²

show clear overlap in receptor binding and they are widely expressed, they exhibit unique functions. These unique features mainly arise from the different affinities with which they bind to their receptors and the restricted expression pattern of those receptors (reviewed in refs. 86, 89).

In addition to constant and ligand-independent tonic signaling via the BCR,^{90, 91} naive mature B lymphocytes critically depend on BAFF – BAFF-R interaction for survival.^{75, 92}

In mice, genetic ablation of BAFF or BAFF-R results in a dramatic reduction in nearly peripheral B-cell subsets.^{93, 94}

TACI appears to have a dual role in B-cell activation. TACI^{-/-} mice have enlarged spleens and lymph nodes, suggesting that TACI functions to regulate B-cell homeostasis.⁹⁵⁻⁹⁷ On the other hand, TACI^{-/-} mice have reduced serum IgM and IgA levels, and they mount a deficient response to type II T-cell independent antigens.⁹⁵ In contrast to BAFF, APRIL can bind TACI and proteoglycans simultaneously. The opposing roles of TACI in B-cell activation could be the result of these two different interactions: TACI acts as a negative regulator of BAFF-induced B-cell responses and a positive regulator of APRIL induced IgA production and humoral responses to T-cell independent antigens.⁹⁸ BCMA was only found expressed on the surface of a proportion of germinal center B cells.⁹⁹ The interaction of BCMA with APRIL is stronger than with BAFF. BCMA^{-/-} mice do not show any B-cell defects,¹⁰⁰ but BCMA appears to be involved in antigen presentation and plasma cell survival.^{101, 102}

2. PRIMARY ANTIBODY DEFICIENCIES

Proper functioning of the complex network of cells and components that form the immune system is required for proper host defence. This is illustrated by patients that suffer from primary immunodeficiencies. These patients have a rare inherited disorder that affects the immune system. As a result, they present with multiple recurrent infections during childhood or as young adult, depending on the defect. In the past five decades, over 120 inherited primary immunodeficiencies have been discovered, which have recently been grouped into eight categories:¹⁰³

1. Combined T- and B-cell immunodeficiencies
2. Predominantly antibody deficiencies
3. Other well-defined immunodeficiency syndromes
4. Diseases of immune dysregulation
5. Congenital defects of phagocyte number, function, or both
6. Defects in innate immunity
7. Autoinflammatory disorders
8. Complement deficiencies

B-cell defects can be found in two categories: 1, 2 and 3. Category 1 contains the B-cell deficiencies that are combined with a T-cell deficiency. Due to the T-cell deficiency, these patients can suffer from severe and often opportunistic infections caused by a wide range of pathogens already in the first months of life. Most deficiencies in this category were

Figure 13. B-cell differentiation blocks in primary immunodeficiency diseases.

Defects in genes encoding V(D)J recombination or pre-BCR signaling components result in a block in precursor-B-cell differentiation prior to the pre-B-II cell stage. ICOS, TAC1 and CD19 (**Chapter V**) deficiencies lead to a defect in B-cell maturation and CD40L, CD40, AID and UNG defects result in impaired CSR and SHM in the germinal center reaction.

previously denoted as severe combined immunodeficiency (SCID). Category 2 concerns B-cell specific deficiencies. These patients are unable to generate a proper antibody response. As a result, they commonly present with multiple recurrent bacterial infections, e.g. of the gut and upper respiratory tract. Category 3 contains syndromes with a defect in the immune system and additional clinical features that are not related to the immunodeficiency. The different types of B-cell defects and affected genes are discussed below and indicated in Figure 13.

V(D)J recombination defects

Defects in the genes required for V(D)J recombination lead to a combined T- and B-cell deficiency and are grouped into category 1 and 3. In these patients, B- and T-cell differentiation are blocked in early stages in bone marrow and thymus due to the inability to produce a functional BCR or TCR. Consequently, hardly any B or T lymphocytes are found in peripheral blood and serum Igs are not detectable. The first defects in these T-B-SCID patients were identified in the *RAG* genes.¹⁰⁴ These patients show a full block in precursor-B-cell differentiation in bone marrow at the pre-B-I cell stage and lack Ig gene rearrangements.¹⁰⁵ Since *RAG* gene expression is restricted to precursor-B and precursor-T cells, these patients have no other clinical features. Hypomorphic mutations in the *RAG* genes that allow restricted residual activity lead to Omenn syndrome. These patients do have peripheral T cells, but in general these are of oligoclonal origin with restricted TCR heterogeneity. In addition to a profound immunodeficiency, these patients commonly have severe atopic dermatitis, histiocytosis X, and symptoms

similar to graft-versus-host disease (GVHD). For diagnosis of Omenn syndrome, maternal T-cell engraftment or transfusion-associated GVHD should be excluded.

More recently, defects in T-B-SCID patients have been identified in three genes encoding proteins involved in dsDNA break repair: Artemis, DNA ligase IV and Cernunnos.^{37, 106, 107} These proteins are expressed in all cell types, where they function in recognition and repair of dsDNA breaks. As a result, patients with a defect in one of these genes are radiation sensitive, which is illustrated by the fact that fibroblasts cultured from the skin of these patients are highly sensitive to ionizing radiation.^{37, 106, 107} Furthermore, patients with DNA ligase IV and Cernunnos deficiencies can present with microcephaly and facial dystrophy.^{107, 108}

Pre-BCR signaling defects

Several defects have been described in genes that form the pre-BCR or that are required for downstream signaling from this receptor. These genes are crucial for proper precursor-B-cell differentiation, and defects result in a profound decrease or absence of B lymphocytes in the periphery and profound decreased serum Ig levels. Previously, this group of patients was classified as agammaglobulinemia. This disease was first described by Bruton in 1952 and seemed to affect only boys, thus suggesting X-linked inheritance.¹⁰⁹ The affected gene was not identified until 1993.^{110, 111} It appeared to be a protein-tyrosine kinase that signals downstream of the pre-BCR, and it was later named BTK. More recent observations indicate that about 85 % of agammaglobulinemia patients are boys that carry a genetic defect in the *BTK* gene on chromosome X.¹¹² In some of the residual cases, genetic defects have been found in *IGHM*,¹¹³ *L14.1*,¹¹⁴ *CD79A*,¹¹⁵ and *BLNK*.¹¹⁶ These defects are all autosomal recessive and are rarely found. Defects in all five genes result in a block in precursor-B-cell differentiation before the pre-B-II cell stage. In *IGHM*-deficient and in *CD79A*-deficient patients, this is a full block, whereas in *L14.1*, *BTK* and *BLNK* deficiencies low numbers of pre-B-II, immature and mature B lymphocytes can be found.

Class switch recombination and/or somatic hypermutation defects

Deficiencies of four genes have been identified that result in a defect in CSR and/or SHM. Previously, these deficiencies were named hyper-IgM syndromes. These patients have normal numbers of B lymphocytes and normal to high levels of serum IgM, but due to defects in CSR, they lack or have strongly reduced serum IgG and IgA.

Originally, the hyper-IgM syndrome was described in boys and the first genetic defects were identified in a gene located on the X-chromosome encoding CD154 (CD40L).¹¹⁷ More recently, an autosomal recessive variant with similar clinical features was shown to be caused by mutations in the gene encoding CD40.¹¹⁸ The CD40 and CD40L are required for, but not restricted to, T-cell dependent B-cell responses, and defects in these genes also affect T-cell and innate immunity. Therefore, in addition to the antibody deficiency, these patients can suffer from neutropenia and opportunistic infections. Consequently, CD40 and CD40L deficiencies have recently been grouped in the combined T- and B-cell immunodeficiencies.¹⁰¹ CD40- and CD40L-deficient patients lack class-switched memory B cells in peripheral blood, whereas they do have CD27⁺IgM⁺IgD⁺ natural effector cells, which are thought to be

recirculating splenic marginal zone B lymphocytes.¹¹⁹ The Ig genes of these natural effector B cells contain somatic hypermutations.⁷² This indicates that CD40-CD40L interaction is required for the germinal center reaction, but not for induction of AID in T-cell independent responses in the marginal zone.^{71, 116}

Defects in *AID* and *UNG* have recently been identified in patients with severely reduced serum IgG and IgA.^{120, 121} These defects result in a B-cell specific defect. Null mutations in *AID* completely abolish both SHM and CSR, whereas hypomorphic mutations have been found that specifically restricts one of the two molecular processes. *UNG*-deficient B cells fail to generate dsDNA breaks in Ig switch regions and cannot undergo CSR. SHM can take place, however, mutations at C and G residues are skewed towards transition mutations.¹²¹

Common variable immunodeficiencies

Although many gene defects have been shown to underlie primary antibody deficiencies, no molecular defect has been found in large groups of immunodeficient patients. This concerns patients with a phenotype that resembles T-B-SCID, agammaglobulinemia or a hyper-IgM syndrome, but also patients with a more diffuse clinical picture. The latter group is currently diagnosed as common variable immunodeficiency (CVID) and includes patients with both childhood and early adult onset of predominantly recurrent bacterial infections. These observations suggest that other genes might be affected than those previously identified to cause antibody deficiency when disrupted. Similar to the identified genes, these as yet unidentified genes might be involved in the V(D)J recombination, pre-BCR signaling, or CSR/SHM processes. However, genes involved in other processes that are critical for B-cell differentiation and antigen maturation might be mutated. Recently, the first monogenetic defects have been identified in CVID patients. A single founder mutation in the *ICOS* gene was found in nine patients, corresponding to <1 % of CVID patients.^{122, 123} *ICOS* is upregulated in T cells and is required for normal germinal center formation. The *ICOS* deficiency therefore results in reduced Ig switched memory B cells, plasma cells and serum IgA and IgG. The majority of the *ICOS*-deficient patients presented in adulthood, suggesting that partly compensatory mechanisms exist to maintain immunity during childhood. The second gene that was found to be associated with CVID is *TACI*.^{124, 125} Whereas patients with homozygous mutations have been found, the majority of identified patients carries a single affected allele and family pedigree analysis indicates autosomal dominant inheritance.¹²⁶ Approximately 8 % of CVID patients carries a mutant *TACI* allele.^{124, 125} In <10 % of antibody deficient patients, a genetic defect has been found that underlies the disease. Patients diagnosed as having CVID present with highly variable susceptibility to and severity of infections. In addition, an increased incidence of autoimmune diseases and malignancies is found in cohorts of CVID patients. The clinical variation restricts optimal individual patient treatment and although patients are currently treated with IgG substitution therapy and (prophylactic) antibodies,¹²⁷ their quality of life is significantly worse than patients with other chronic illnesses.¹²⁸

3. GENOMIC MUTATIONS IN HUMAN DISEASE

Genomic mutations underlie human inherited diseases, such as primary immunodeficiencies. Characterization of the gene lesions resulted in the identification of multiple different types of mutation: single base pair substitutions, deletions, insertions, duplications, inversions, and repeat expansions. Functional studies to address the mechanism underlying these mutations are difficult to perform and data on this topic is scarce. However, molecular data on disease-causing mutations is widely available thanks to inclusion in databases, either genome-wide (Online Mendelian Inheritance in Man; OMIM,¹²⁹ and Human Gene Mutation Database; HGMD),¹³⁰ or gene-specific (e.g. immunodeficiency mutation databases; IDbases).¹³¹ The collected data on disease-causing mutations allows sequence analysis for common motifs in order to identify the processes mediating the mutations.

Within the total group of disease-causing mutations, a crude division is made between small lesions (<20 bp) and gross lesions. Small lesions include single-base-pair substitutions, micro-deletions (<20 bp), micro-insertions (<20 bp) and micro-indels (<20 bp). Indels are lesions, in which one or more nucleotides were deleted and the same or a different number of new nucleotides were inserted. Recent analysis of the mutations recorded in HGMD showed that single basepair substitutions are most frequently observed: 68 % of all mutations (Figure 14). This is clearly more than micro-deletions (16 %), micro-insertions (7 %) and micro-indels (1.5 %).

In 2000, Antonarakis and colleagues performed a detailed analysis of small lesions recorded in HGMD.¹³² They found a significant excess of transition (purine - purine or pyrimidine - pyrimidine exchange) over transversion (purine - pyrimidine exchange) mutations as compared

Figure 14. Spectrum of the different types of human gene mutations recorded in the human genome mutation database (HGMD) as of 3 January 2007 containing 67030 mutations.

Micro-lesions are the most commonly found gene disruptions underlying human disease, with the vast majority being single base pair substitution. Although not common, a substantial number of gross lesions has been identified. The majority of these are gross deletions.

to random expectation. This was mainly, but not solely, affected by the hypermutability of the CG dinucleotide to TG or CA. Nucleotide substitutions are thought to occur in a non-randomly throughout the genome.^{133, 134} Especially CG dinucleotides have an increased susceptibility to be mutated, and has been observed in a wide range of human genes.¹³⁵⁻¹³⁸ This is thought to be related to the methylation of the cytosine in CG dinucleotides.¹³⁹ Deamination of cytosine results in uracil, whereas deamination of 5-methylcytosine results in a thymidine residue. Uracil is recognized and excised by uracil DNA glycosylase. However, thymidine is not specifically excised, as it is one of the four natural bases in DNA. Thus, methylated CG dinucleotides have increased mutation susceptibility into TG or CA.

Micro-deletions and -insertions are associated with short repeats that are usually between 2 and 8 bp.¹⁴⁰ These elements can be direct repeats, palindromes (inverted repeats) and symmetric elements. Most proposed mechanisms that underlie microdeletions are based on the slipped-mispairing hypothesis,¹⁴¹ which states that during replication one DNA strand can be misaligned via a repeat sequence with the complementary strand.^{142, 143} The resulting loop structure can be excised thereby generating the small deletion. This type of deletion is induced by mutagens.¹⁴⁴

Gross lesions (>20 bp) include gross deletions (6 % of total deleterious mutations), gross insertions (1 %), repeat variations (0.2 %), or other complex rearrangements (1 %) such as inversions. The exact molecular mechanisms by which gross lesions arise are not completely understood, but based on limited sequence data of gross deletion junctions in disease-causing alleles, three mechanisms resulting in gross deletions have been proposed: 1) Mispairing of homologous sequences and unequal crossing over; 2) Non-homologous deletions; 3) Mispairing between short repeat elements and crossing-over.¹⁴⁵ Non-homologous gross deletion breakpoints that fall in the latter two categories are frequently located in or near interspersed repeat elements.¹⁴⁶

Whereas coding sequences comprise only 5 % of the human genome, repeat sequences account for at least 50 %.¹⁴⁷ The majority of these sequences are transposon-derived repeats (interspersed elements). In mammals, four classes of transposon-derived repeats can be identified, which make up about 45 % of the total sequence (Figure 15). DNA transposons

			Length	Copy number	Fraction of genome
1. LINES	Autonomous		6-8 kb	1,210,000	16%
2. SINEs	Non-autonomous		100-300 bp	1,560,000	11%
3. ERVs	Autonomous		6-11 kb	714,000	7%
	Non-autonomous		1.5-3 kb		
4. DNA transposon fossils	Autonomous		2-3 kb	370,000	3%
	Non-autonomous		80-3,000 bp		

Figure 15. Classes of transposon-derived elements in the human genome.

Four main classes of transposable elements can be identified based on their functional characteristics. Three of these, LINES, SINEs and ERVs, transpose with RNA intermediates, whereas the fourth, DNA transposons, does not. Figure modified from Lander *et al.*;¹⁴⁷ the copy numbers and fraction of genome for each class were determined on the human genome sequence in December 2006 using the CENSOR software tool of the Repbase database in normal mode.¹⁴⁸

transpose directly as DNA, whereas LTR retrotransposons, long and short interspersed elements (LINE and SINE) transpose via RNA intermediates. LINES are autonomous elements; they harbor an internal polymerase II promoter to generate transcripts. These transcripts encode two proteins that assemble with the transcript and display reverse transcriptase activity enabling integration of RNA transcripts in genomic DNA. Of the three LINE families (LINE1-3), only LINE1 elements are still active.

SINEs harbor an internal polymerase III promoter, but do not contain an open reading frame (ORF). Consequently, these elements cannot transpose autonomously. They are thought to use the LINE1 machinery for transposition. Of the three SINE families in the human genome, Alu elements are active, whereas MIR and MIR3 are not.

Full-length LTR retrotransposons are autonomous. They contain long terminal 5' and 3' direct repeats that contain transcriptional regulatory elements. Furthermore, LTR retrotransposons contain the *GAG* and *POL* genes that mediate the integration of RNA intermediates in genomic DNA. In mammals, the only active LTR retrotransposons are endogenous retroviruses (ERV), which fall into three classes (I-III).

DNA transposons have terminal inverted repeats that flank the transposase-encoding gene. The transposase recognizes the inverted repeats and is able to cut the DNA transposon from the genome and paste it in a different position without forming an RNA intermediate.

4. AIMS OF THE THESIS

B lymphocytes and the immunoglobulins they produce are critical components of the immune system. This is illustrated by patients with primary antibody deficiency. These patients have a defect in the generation of B lymphocytes or in the production of immunoglobulins by their B lymphocytes. Genetic disruption of a single gene is often the cause of the disease. Although in the past 15 years defects in multiple genes have been identified in patients with primary antibody deficiency, in many cases a molecular diagnosis has not been made. In order to identify the disrupted gene, a better understanding of B-cell differentiation is required.

Primary antibody deficient patients in whom the underlying genetic defect has been identified provide the unique opportunity to study the role of a single protein in the immune system. Studying this defect will result in better understanding of the human immune system. Subsequently, this knowledge can be applied to develop novel approaches to increase the efficiency and accuracy of diagnosis and chronic treatment of patients with primary immunodeficiency.

This thesis describes studies aimed at understanding important checkpoints and key players in B-cell differentiation and defects underlying primary antibody deficient patients. **Chapter II** describes the initiation of *IGH* and *IGK/IGL* rearrangements in human precursor-B-cell differentiation and the networks of factors that might be involved. In **Chapter III**, mouse models are used to visualize the *IGH* locus conformation in early lymphoid and B-progenitor cells. Large-scale compaction of *IGH* is required for V(D)J recombination, but the underlying mechanisms are largely unknown. The majority of human disease-causing gene disruptions are small lesions. This is not the case for several genes disrupted in primary immunodeficiencies and leading to a block in precursor-B-cell differentiation. **Chapter IV**

describes gross deletions in primary immunodeficiency genes and potential mechanisms that mediate these deletions. In **Chapter V**, a novel antibody deficiency syndrome is described in four patients due to mutations in *CD19*. Immunological studies were performed to identify the B-cell defects. The contribution of proliferation to naive B-lymphocyte homeostasis and antigen-induced B-cell expansion are described in **Chapter VI**. The **General Discussion** deals with the implications of the studies described in this thesis and with directions for future research.

ABSTRACT

The role of specific transcription factors in the initiation and regulation of Ig gene rearrangements has been studied extensively in mouse models, but data on normal human precursor-B-cell differentiation are limited. We purified five human precursor-B-cell subsets, and assessed and quantified their *IGH*, *IGK* and *IGL* gene rearrangement patterns and gene expression profiles. Pro-B cells already massively initiate D_H-J_H rearrangements, which are completed with V_H-D_H rearrangements in pre-B-I cells. Large cycling pre-B-II cells are selected for in-frame *IGH* gene rearrangements. The first *IGK/IGL* gene rearrangements were initiated in pre-B-I cells, but their frequency increased enormously in small pre-B-II cells, and in-frame selection was found in immature B cells. Transcripts of the *RAG1* and *RAG2* genes, and earlier defined transcription factors, such as *E2A*, *EBF*, *E2-2*, *PAX5* and *IRF4*, were specifically up-regulated at stages undergoing Ig gene rearrangements. Based on the combined Ig gene rearrangement status and gene expression profiles of consecutive precursor-B-cell subsets, we identified 16 candidate genes involved in initiation and/or regulation of Ig gene rearrangements. These analyses provide new insights into early human precursor-B-cell differentiation steps and represent an excellent template for studies on oncogenic transformation in precursor-B-cell acute lymphoblastic leukemia and B-cell differentiation blocks in primary antibody deficiencies.

INTRODUCTION

Precursor-B cells develop from hematopoietic stem cells and differentiate through a number of stages in the bone marrow (BM) before they migrate to the periphery as naive mature B lymphocytes. The ultimate purpose of B-cell differentiation is to produce the broad repertoire of B-cell antigen receptors (BCR), which are composed of two identical Ig heavy chains and two identical Ig light chains (reviewed in Ref. 1). Early in differentiation, V(D)J recombination is initiated in the Ig heavy chain (*IGH*) locus with D_H to J_H rearrangements in pro-B cells. The lymphocyte-specific RAG1 and RAG2 proteins introduce a single stranded nick between the recombination signal sequence (RSS) and the flanking D or J gene segment, which results in the generation of a dsDNA break.^{2, 3} The DNA-bending high mobility group proteins HMGB1 and HMGB2 stimulate the RAG proteins in DNA binding and the generation of the dsDNA breaks,⁴ which are subsequently repaired via non-homologous end joining (NHEJ).⁵ In the next stage (pre-B-I), a V_H segment is rearranged to the DJ_H element, and if an in-frame VDJ_H exon is formed, a pre-BCR is expressed, which is composed of IgH chains and surrogate light chains (VpreB and $\lambda 14.1$). The expression of this receptor initiates several cycles of proliferation (large cycling pre-B-II cell stage). After this proliferation phase, Ig light chain rearrangements are initiated in the small pre-B-II cells. If a functional Ig light chain (Ig κ or Ig λ) is expressed that is able to assemble with the IgH chain, the cell becomes a surface membrane (Sm)Ig $^+$ immature B cell. If this cell is non-autoreactive, it migrates to the periphery as a naive mature B cell.

The differential expression of marker molecules is used to define the main stages of B-cell differentiation. Five main human precursor-B-cell differentiation stages can be recognized using the following markers: 1) CD22 $^+$ CD19 $^-$ pro-B cells; 2) CD19 $^+$ cytoplasmic (Cy)Ig μ^- pre-B-I cells; 3) CyIg μ^+ VpreB $^+$ pre-B-II large cells; 4) CyIg μ^+ VpreB $^-$ pre-B-II small cells; 5) SmIgM $^+$ immature B cells. Naive mature B lymphocytes in the periphery are SmIgM $^+$ SmIgD $^+$.^{6, 7}

Although there is a common V(D)J recombinase machinery, Ig gene rearrangements are separated in time and restricted to one locus. Transcription factors PAX5, early B-cell factor (EBF), and the E-box proteins E2A, HEB and E2-2 appear to act in a hierarchical order for commitment to B-cell fate and the initiation of Ig gene rearrangements by opening Ig loci,⁸⁻¹² and by inducing expression of recombination-related proteins (RAG1, RAG2, TdT) and (pre-)BCR proteins (VpreB, $\lambda 14.1$, CD79A).¹³⁻¹⁶ The Ets transcription factor PU.1 is required for generation of lymphoid as well as myeloid cells,^{17, 18} and is suggested to be the partner of IRF4 and IRF8 in large pre-B cells, where they inhibit proliferation and initiate Ig light chain rearrangements.^{19, 20} In addition, histone remodeling factors EZH2 and BRG1, and DNA demethylases are likely to be involved in the induction of Ig gene rearrangements.²¹⁻²³

The majority of our understanding of the initiation and regulation of Ig gene rearrangements in precursor-B-cell differentiation comes from studies in mouse models, and genome-wide gene expression profiling has been performed exclusively in murine precursor-B cells.^{24, 25} However, these studies did not show how V(D)J recombination is strictly regulated per locus in each specific stage of differentiation.

Therefore, we aimed at purifying cells in the five main stages of human precursor-B-cell differentiation, thus creating the opportunity to study the initiation of *IGH* and

IGK/IGL rearrangements independently from each other and independently from the selection processes. The precursor-B-cell subsets were purified with membrane markers only, to allow both DNA extraction for analysis of the Ig gene rearrangements using real-time quantitative (RQ-)PCR and GeneScan assays, and RNA extraction for genome-wide gene expression profiling using Affymetrix GeneChip arrays. This approach enabled us for the first time to study the networks of factors that might be involved in the initiation and regulation of V(D)J recombination processes in the different Ig loci in human precursor-B-cell differentiation.

MATERIALS AND METHODS

Purification of CD34⁺lin⁻ and (precursor-)B-cell populations

Precursor-B cells were obtained from freshly isolated BM samples of healthy children (age 3-16), who served as donors for BM transplantation in a sibling. The BM samples were taken for quality control of the graft. Remaining BM (generally 0.5-2.0 ml) was used for the precursor-B-cell studies. CD34⁺lin⁻ cells were obtained from umbilical cord blood (UCB), because it was not possible to obtain enough CD34⁺lin⁻ cells from BM samples.

For isolation of CD34⁺lin⁻ cells and pro-B cells, MACS CD34 beads (Miltenyi Biotec, Cologne, Germany) were used to positively select CD34⁺ progenitor cells. CD34⁺lin⁻ cells were further purified by sorting on a FACSDiVa cell sorter (BD Biosciences, Santa Clara, CA) after labeling with CD34-APC (8G12), and CD3-PE (Leu-4), CD16-PE (B73.1), CD19-PE (4G7), CD56-PE (M431; all from BD Biosciences), CD13-RDI (MY7), CD33-RDI (906; both from Beckman Coulter, Fullerton, CA) for exclusion. Pro-B cells were further purified after labeling with CD34-FITC, CD19-PE, CD123-PE (9F5), and CD22-APC (S-HCL-1; all from BD Biosciences). Four CD19⁺ precursor-B-cell subsets were MACS sorted using CD19 beads (Miltenyi Biotec) and staining with CD34-FITC, CD20-PE (Leu-16), CD10-APC (HI10a; both from BD Biosciences), and anti-IgM-Cy5 (Jackson ImmunoResearch Laboratories, Inc, West Grove, PA). Additional markers for defining and characterization of the precursor-B-cell fractions were: Ki67-FITC, anti-Igκ-FITC (both from DakoCytomation, Glostrup, Denmark), anti-Igλ-PE (Southern Biotechnology Associates, Inc, Birmingham, AL) and CD79b-PE (SN8; BD Biosciences). All fractions were collected in 2 ml tubes containing filtered heat-inactivated FCS and were kept at 4°C until reanalysis on a FACSCalibur (BD Biosciences) and subsequent isolation of DNA and/or RNA.

Mature Igκ⁺ and Igλ⁺ B lymphocytes were sorted after mechanical disruption of tonsillar tissue obtained from children, Ficoll density centrifugation, and direct staining with anti-Igκ-FITC, anti-Igλ-PE and CD19-APC (SJ25C1; BD Biosciences).

When possible, DNA and RNA were isolated from subsets of three donors. DNA was isolated twice for CD34⁺lin⁻, pro-B, mature Igκ⁺ and mature Igλ⁺ B cells. RNA was isolated twice from CD34⁺lin⁻ and large pre-B cells, and once from pro-B cells. All fractions were obtained with a purity of >95 %.

All cell samples were obtained according to the informed consent guidelines of the Medical Ethics Committees of the University Medical Center Utrecht, the Leiden University Medical Center and the Erasmus MC, University Medical Center Rotterdam.

Real-time quantitative PCR (RQ-PCR) and GeneScan analysis of Ig gene rearrangements

A multiplex TaqMan-based RQ-PCR was used to quantify *IGH*, *IGK* and *IGL* gene rearrangements. Family-specific V- and D-segment forward primers, J-segment specific reverse primers, and J-segment specific probes were newly designed or adapted in such a way that >95 % of all rearrangements could be detected (Appendix 1).²⁶⁻³¹ The RQ-PCR mixture of 25 μ l contained TaqMan Universal MasterMix (Applied Biosystems, Foster City, CA), 900 nM of each primer (300 nM in case of multiplex mixtures), 100 nM of each FAM-TAMRA labeled probe, 50 ng of DNA, 0.4 ng BSA, and was run on the ABIPRISM 7700 sequence detection system (Applied Biosystems).^{32, 33}

An albumin RQ-PCR was used for quantification of the DNA input.³⁴ For quantification of the Ig gene rearrangement, a standard curve was made on a 10-fold dilution series of DNA from one or more cell lines harboring monoallelic Ig gene rearrangements, diluted in a background of germline (un-rearranged) DNA (total input 50 ng). Each assay reproducibly reached a sensitivity of at least 1 % rearrangement in germline background and was performed in duplicate on each DNA sample. The rearrangements were quantified relative to the monoallelically rearranged control cell lines, which were set at 100 %. Consequently, it is possible to measure a level of 200 % rearrangements in a cell population with all cells having biallelic rearrangements.

To analyze the in-frame selection of Ig gene rearrangements in precursor-B-cell subsets, complete *IGH*, *IGK* and *IGL* rearrangements were amplified and subjected to GeneScan analysis with modified V-segment forward primers, positioned in such a way that in-frame rearrangements result in triplet spacing of the GeneScan peaks (Appendix 2).³⁰

RNA isolation and gene expression profiling

RNA isolation and gene expression profiling were essentially performed as described before,³⁵ and according to MIAME guidelines,³⁶ using Affymetrix HG-U133 set GeneChip arrays and corresponding hybridization, washing and scanning equipment Affymetrix, Santa Clara, CA).

Due to the limited amount of material, 100 ng of total RNA was subjected to two cycles of *in vitro* transcription according to the Affymetrix “small sample target labeling assay”, version 2. The scaling factor, noise, and presence calls were comparable between all samples. GeneChip array data was quantile normalized,³⁷ and background was removed using robust multichip analysis.³⁸ Array groups corresponding to the development stages were compared based on the perfect match probe intensity levels only,³⁸ by performing a per-probe set two-way analysis of variance (ANOVA, with factors “probe” and “stage”). This resulted in average expression levels for each probe set in each stage as well as *p*-values for the significance of the difference between the stages. The *p*-values were adjusted for multiple testing using Šidák step-down adjustment,³⁹ and all differences with adjusted *p*-values < 0.05 were considered significant, resulting in 5,365 significant probe sets. All raw GeneChip array data are freely available at <http://franklin.et.tudelft.nl/>.

Selection of genes likely to be involved in the initiation and regulation of Ig gene rearrangements

The expression values of the 5,365 significant probe sets were normalized per-probe set to zero mean and unit standard deviation (*z*-score). Hierarchical clustering (complete linkage) based on Pearson correlation was then performed on the significant probe sets using the Genlab software toolbox (www.genlab.tudelft.nl), running in the Matlab programming environment. The Gene Ontology (GO) Consortium website (<http://www.godatabase.org>) was used to select, within the significant probe sets, for probe sets annotated with GO terms representing genes involved in regulation of transcription, DNA recombination, and DNA repair: GO:3676, GO:3677, GO:3684, GO:3700, GO:3712, GO:3713, GO:3714, GO:5667, GO:6266, GO:6281, GO:6282, GO:6302, GO:6303, GO:6310, GO:6350, GO:6351, GO:6355, GO:6366, GO:6367, GO:16481, GO:16563, GO:16564, GO:45739, GO:45941. Genes not involved in regulation of transcription, DNA recombination and DNA repair, such as RNA-editing enzymes and histones, were manually removed from the list.

Confirmation of gene expression patterns by RQ-PCR

To confirm the gene expression patterns of the *RAG* genes and 16 newly identified genes in the isolated populations, RNA was reverse transcribed into cDNA, and RQ-PCR was performed with newly designed primers and FAM-TAMRA-labeled probes (Appendix 3). The expression levels were corrected by comparison with control genes *Abelson (ABL)* and beta-glucuronidase (*GUSB*) as described previously.⁴⁰ The expression values of the genes were normalized per-gene to zero mean and unit standard deviation (*z*-score).

RESULTS

Isolation of stem cell-like and (precursor-)B-cell populations

The objective of this study was to correlate Ig gene rearrangements with gene expression profiles in human B-cell differentiation. Therefore, only membrane markers were used for isolation of the relevant cell populations in order to reliably obtain both DNA and RNA from these cells (Figure 1). Stem cell-like CD34⁺lin⁻ (defined as CD3⁻CD13⁻CD19⁻CD33⁻CD56⁻) cells from UCB and pro-B cells (CD22⁺CD34⁺CD19⁻) could be isolated directly using previously established markers. However, for the remaining subpopulations, alternative markers CD10, CD20 and CD34 were required instead of cytoplasmic VpreB or cyIgμ. CyIgμ⁻ pre-B-I cells were isolated based on the phenotype: CD19⁺CD34⁺CD10⁺CD20⁻. In addition, large cycling pre-B-II cells (CD19⁺CD34⁻CD10⁺CD20^{dim}IgM⁻), small pre-B-II cells (CD19⁺CD34⁻CD10⁺CD20⁻), and immature B cells (CD19⁺CD34⁻CD10⁺CD20^{hi}) were isolated. Mature B lymphocytes (CD19⁺CD20⁺) were obtained from tonsillar tissue and separated in either Smlgκ⁺ or Smlgλ⁺ populations based on membrane Ig light chain expression (Figure 1).

Incomplete DH–JH gene rearrangements are initiated in pro-B cells, directly followed by complete VH–DJH rearrangements in pre-B-I cells

The human *IGH* locus contains 66 rearrangeable V, 27 D, and 6 J gene segments (Figure 2A) that can be involved in rearrangements in B cells to form a VDJH exon.

Figure 1. Isolation of CD34⁺lin⁻ and (precursor-)B-cell subsets using membrane markers only. The subsets studied here, their origin, and the markers that were used to isolate them are indicated.

Two multiplex RQ-PCR assays were designed that recognize nearly all these gene segments for both the incomplete (D_H-J_H) and complete (V_H-D_H) rearrangements. No D_H-J_H rearrangements were found in DNA of CD34⁺lin⁻ cells, but they were abundantly present in pro-B, pre-B-I and large pre-B-II cells (Figure 2B). In all subsequent stages the percentage of D_H-J_H rearrangements was lower, due to initiation of V_H-D_H rearrangements, which results in loss of the intron sequence upstream of the D segments in which the forward D_H primers are located. V_H-D_H rearrangements were not detectable until the pre-B-I stage (Figure 2C). In large pre-B-II cells the frequency of V_H-D_H rearrangements reached its maximum and remained constant in all subsequent stages.

These results show that already in the first stage of precursor-B-cell differentiation a large number of incomplete *IGH* rearrangements are formed. This is directly followed by complete V_H-D_H rearrangements in pre-B-I cells, which reach maximal levels in large pre-B-II cells.

***IGK* and *IGL* rearrangements are initiated in small pre-B-II cells, but Vλ-Jλ rearrangements are rare in mature Igκ⁺ B cells**

The human *IGK* locus contains 76 rearrangeable Vκ and 5 Jκ gene segments. In addition to the Vκ-Jκ rearrangements there are two types of *IGK* deleting rearrangements involving the kappa-deleting element (Kde) that make the *IGK* allele non-functional.⁴¹ Vκ-Kde rearrangements can delete an initial Vκ-Jκ and the Cκ exon. Kde can also rearrange to the intronRSS, which is located in between Jκ5 and Cκ. The intronRSS-Kde rearrangement deletes Cκ, but keeps the initial Vκ-Jκ rearrangement present on the locus (Figure 3A).

In CD34⁺lin⁻, pro-B, pre-B-I and large pre-B-II cells, Vκ-Jκ rearrangements were barely detectable (Figure 3B). An enormous increase was found in small pre-B-II and immature B cells, which represented approximately 75 % of the frequency of Vκ-Jκ rearrangements

A. IGH gene complex (14q32.3)

Figure 2. Incomplete D_H-J_H gene rearrangements are initiated in pro-B cells and are directly followed by complete V_H-D_H rearrangements in pre-B-I cells.

A. Organization of the human *IGH* locus; **B.** D_H-J_H rearrangements were quantified in all isolated subpopulations in two separate multiplex TaqMan RQ-PCR assays with primers and probes that detect most members of the six main D_H gene segment families and the six J_H gene segments; **C.** Quantification of V_H-D_H rearrangements in two separate multiplex TaqMan RQ-PCR assays using primers that recognize most members of the seven V_H gene segment families and the six J_H gene segments. Data are obtained from duplicate experiments in two to three donor samples and are quantified (mean ± SD) relative to (a mixture of) monoallelically rearranged control cell lines.

observed in mature Igκ⁺ B cells. The majority of the Vκ-Kde and the intronRSS-Kde rearrangements were induced in pre-B-II small cells as well. In contrast to Vκ-Jκ rearrangements, the Kde rearrangements occurred at low frequency in mature Igκ⁺ B cells. The fact that they occurred at maximal levels in mature Igλ⁺ B cells (Figure 3, C and D) indicates that most *IGK* alleles are deleted in mature Igλ⁺ B cells.

The human *IGL* locus consists of 56 rearrangeable V gene segments and 7 Jλ-Cλ clusters (Figure 4A), of which Jλ1-3 are used in 99 % of the Vλ-Jλ rearrangements.⁴² The Vλ-Jλ rearrangements in precursor-B-cell subsets showed the same pattern as Vκ-Jκ, but the levels of Vλ-Jλ rearrangements appeared to be lower and were about half of the Vλ-Jλ levels in mature Igλ⁺ B cells (Figure 4B). The absence of Vλ-Jλ rearrangements in mature Igκ⁺ B cells (<5 %) indicated that most *IGL* rearrangements were initiated only if no functional Igκ chain could be formed.

Complete V-(D)J rearrangements are followed by in-frame selection

After complete V-(D)J recombination, only B cells with in-frame rearrangements, expressing functional proteins are selected (positive selection). Due to exonuclease activity and random non-templated (N)-nucleotide addition by TdT, the size of the junctional

A. *IGK* gene complex (2p11.2)

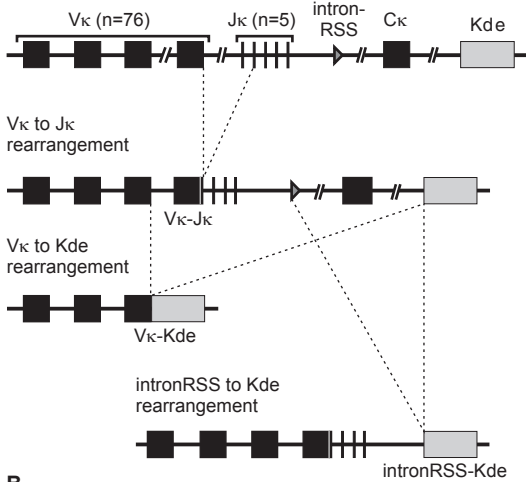

Figure 3. The vast majority of V κ -J κ and Kde rearrangements are initiated in small pre-B-II cells.

A. Organization of the human *IGK* locus and the V κ -J κ and the Kde rearrangements (V κ -Kde and intronRSS-Kde); **B.** V κ -J κ rearrangements were quantified in all isolated subpopulations in a single multiplex TaqMan RQ-PCR assay with primers and probes that detect most members of seven V κ gene segment families and the five J κ gene segments; **C.** V κ -Kde and intronRSS-Kde rearrangements were quantified in the isolated subpopulations in two separate TaqMan RQ-PCR assays with primers and probes that detect most members of seven V κ gene segment families, intronRSS and Kde. The Kde assays were not performed on pro-B cells due to limited availability of material. Data are obtained from duplicate experiments in two to three donor samples and are quantified (mean \pm SD) relative to (a mixture of) monoallelically rearranged control cell lines. The y-axis of panel B is extended to 200 %, because the amount of V κ -J κ rearrangements exceeds the 100 % level in several stages, indicating the presence of biallelic rearrangements.

A. *IGL* gene complex (22q11.2)

B.

Figure 4. The vast majority of Vλ–Jλ rearrangements are initiated in small pre-B-II cells, but seem to occur only after rearrangement of the *IGK* alleles.

A. Organization of the human *IGL* locus; **B.** Vλ–Jλ rearrangements were quantified for all isolated subpopulations in a single multiplex TaqMan RQ-PCR assay with primers and probes that detect most members of the three most frequently used Vλ gene segment families and the three dominant Jλ gene segments. Data are obtained from duplicate experiments in two to three donor samples and are quantified (mean ± SD) relative to a mixture of monoallelically rearranged control cell lines.

region is variable and only one-third of the rearrangements is in-frame. Using GeneScan analysis, the V_H–D_{JH}, V_κ–J_κ, and Vλ–Jλ rearrangements were evaluated for the size of the junctional regions in the (precursor-)B-cell subsets in which these rearrangements were found previously with RQ-PCR. Complete V_H–D_{JH} rearrangements were present in pre-B-I cells, but the size distribution of the junctional regions showed a merely random pattern. In large pre-B-II cells and all subsequent stages the GeneScan pattern was symmetric unimodal with peaks at every third nucleotide (triplet peaks), representing in-frame rearrangements (Figure 5A). These results show that in-frame selection of V_H–D_{JH} rearrangements apparently was completed in large pre-B-II cells.

The GeneScan patterns of the *IGK/IGL* gene rearrangements showed a smaller size of the junctional regions distribution than in case of *IGH*, due to absence of D gene segments and lower levels of N-nucleotide insertion (Figure 5, B and C). In agreement with the RQ-PCR results, pre-B-I and large pre-B-II cells hardly contained V_κ–J_κ and Vλ–Jλ rearrangements. Interestingly, the average size of the V_κ–J_κ junctional regions, but not the Vλ–Jλ junctional regions, was larger in the pre-B-I and large pre-B-II subsets compared to subsequent stages. The size distribution of the junctional regions in small pre-B-II cells was unimodal without triplet peaks, but in immature B cells some triplet peaks could be identified for both V_κ–J_κ and Vλ–Jλ, indicating that immature B cells have undergone in-frame selection. Mature Igκ⁺ B cells showed more clear triplet peaks for V_κ–J_κ rearrangements, whereas mature Igλ⁺ B cells showed triplet peaks for Vλ–Jλ rearrangements, but not for V_κ–J_κ rearrangements. The triplet peaks of the V_κ–J_κ and the Vλ–Jλ rearrangements in immature B cells were less easily identifiable compared to mature Igκ⁺ B cells and Igλ⁺ B cells, respectively, because the immature B-cell subset consisted of a mixture of Igκ⁺ and Igλ⁺ B cells.

Figure 5. In-frame selection of *IGH* and *IGK/IGL* gene rearrangements occurs in the stage directly after initiation of the respective complete rearrangements.

Analysis of in-frame selection on V_H-DJ_H , V_K-J_K , V_L-J_L rearrangements using GeneScan analysis, as assessed via triplet peaks, of which the position is indicated at the bottom of each panel. In addition to the size distribution of the junctional regions, the internal size standard peaks are shown. The triplet peaks of V_K-J_K and V_L-J_L rearrangements were most clear in mature Igk^+ and Igl^+ B cells, respectively. In immature B cells, the triplet peaks were less visible because this was a mixture of Igk^+ and Igl^+ B cells. Data are representative of two or three independent experiments.

Gene expression profiling of precursor-B-cell populations

Gene expression profiles of CD34⁺lin⁻ cells from UCB and the five main precursor-B-cell subsets from BM were determined on several biological repeats using the Affymetrix HG-U133 set GeneChip arrays that contain 45,000 probe sets. The six subsets were distinguished by the significant differential expression of 5,365 probe sets that were at least once differentially expressed between two subsequent stages of differentiation (Figure 6A and Supplemental Table I, online). Hierarchical clustering was performed to group the expression patterns in 18 different clusters (Figure 6, A and B).

The expression patterns were determined of a number of genes encoding proteins that have been described to function in human and/or murine precursor-B-cell differentiation (Figure 6B and Supplemental Table II, online). The gene expression patterns of the markers that were used to isolate the six subsets (*CD34*, *CD19*, *CD10*, *CD22*, *CD20*, and *KI67*) corresponded well with their protein expression (Figure 6B and Supplemental Table II, online). Stem cell markers (*FLT3*, *KIT*), myeloid genes (*MPO*) and T-cell receptor germline transcripts were down-regulated from stem cells to early stages of B-cell differentiation. Inversely, B-cell commitment transcription factors (*E2A*, *EBF*, *E2-2*, *PU.1* and *PAX5*) were found to be up-regulated early in B-cell differentiation. These transcription factors are involved in opening of Ig loci and positively regulate transcription of (pre)-BCR complex and signaling molecules. Polycomb protein *EZH2* and chromatin remodeling protein *BRG1*, which are implicated in complete *IGH* gene rearrangements, were highly expressed in pre-B-I cells. *IGHM*, *IGKC*, and *IGLC* transcripts were already up-regulated early in B-cell differentiation, even before

Figure 6. Gene expression profiling of human CD34⁺lin⁻ and precursor-B-cell subsets.

A. (facing page) Heat map with the normalized data of significantly differentially expressed probe sets. The expression patterns were grouped into 18 clusters; **B.** Expression pattern of all probe sets per cluster are shown as mean with SD. For each cluster, the total number of genes and the names of several genes reported to be involved in precursor-B-cell differentiation or commitment to other hematopoietic lineages are shown. A few genes can be found in several clusters, when multiple probe sets representing the same gene showed different expression patterns; within each cluster a gene is displayed only once. The following genes were studied as well, but were not found to be differentially expressed: *ARTEMIS*, *HEB*, *ID1*, *ID4*, *NOTCH1*, *PLCG2*, *STAT5A*, *TCRA/D*, *XRCC4*, *IKAROS*, *HELIOS*, *AIOLOS*.

Ig gene rearrangements were found. These early transcripts were most likely germline transcripts. Transcripts of (pre-)BCR complex members *L14.1*, *VPREB1*, *CD79A* and *CD79B* were significantly up-regulated in large pre-B-II cells, and the same was seen for many (pre-) BCR signaling molecules, such as *BTK*, *SYK* and *LYN*. HMG-box proteins *LEF1* and *SOX4* were highly expressed in both pre-B-I and pre-B-II small, whereas *IRF4* and *IRF8* were up-regulated in large pre-B-II and immature B cells, respectively. A number of genes were recognized by multiple probe sets, which showed a slightly different expression pattern and were therefore in some cases assigned to more than one cluster.

The expression patterns of *RAG1* and *RAG2* showed peaks in pre-B-I and small pre-B-II cells, the populations in which complete *IGH* and *IGK/IGL* gene rearrangements are formed, respectively. *HMGB1* and *HMGB2* expression was high throughout B-cell development with a peak in pre-B-I and large pre-B-II cells. *TdT* expression was high only in pro-B and pre-B-I cells and not in small pre-B-II cells that undergo *IGK/IGL* gene rearrangements. Genes encoding proteins involved in recognition of dsDNA breaks induced by cleavage of the RAG proteins (*KU70*, *KU80*, *DNA-PKcs*) were found to be specifically up-regulated in one or more stages of B-cell differentiation undergoing Ig gene rearrangements. DNA ligase IV (*LIG4*) was the only member of the NHEJ dsDNA break repair machinery that was differentially expressed in parallel to *RAG1* and *RAG2* with peaks of expression in pre-B-I and small pre-B-II cells.

We have thus shown that the expression of well-defined B-cell differentiation and V(D)J recombination-associated genes correlated well with the rearrangement status of the precursor-B-cell subsets. This provides a firm basis to identify molecules that are likely to be involved in the initiation and regulation of the Ig gene rearrangements.

Initiation and regulation of Ig gene rearrangements

A restricted set of GO terms of the Gene Ontology Consortium was used to select for categories of genes required for V(D)J recombination: (1) DNA-binding transcription factors; (2) enzymes involved in DNA methylation; (3) histone and chromatin remodeling factors; (4) recombination-related enzymes; (5) DNA repair molecules. This yielded a set of 476 genes that were at least once differentially expressed between two subsequent stages in differentiation (Figure 7 and Supplemental Table III, online). From CD34⁺lin⁻ to pro-B cells, about the same number of genes (~35 genes) were up-regulated as were down-regulated. This was clearly not the case for the transition from pro-B to pre-B-I where complete *IGH* rearrangements are initiated; almost four times as many genes were up-regulated (143 genes) than down-regulated (40 genes). In contrast, twice as many selected genes were down-regulated rather than up-regulated in the transitions from pre-B-I to large pre-B-II (155 vs. 85 genes) and from small pre-B-II to immature B (71 vs. 39 genes). Interestingly, this indicates a trend that many transcription-related genes are down-regulated in subsets undergoing selection compared with subsets undergoing V(D)J recombination.

The prototypes of nine of the eighteen defined clusters (Figure 6B) showed peaks in pro-B, pre-B-I and/or small pre-B-II cells during which D_H-J_H, V_H-D_{JH} and V_L-J_L rearrangements take place, respectively. Therefore, these clusters were more likely to contain genes that are involved in the initiation of Ig gene rearrangements than the other nine clusters (Table I). These nine clusters contained 243 genes, of which most belong to families of

transcription factors based on sequence and/or functional homology. Most genes shown in Table I contained zinc fingers and were related to the Krüppel-like factor (KLF) family of DNA-binding transcriptional regulators. A large number of zinc finger proteins were annotated solely based on sequence homology and due to the lack of additional data from literature they will not be further considered here.

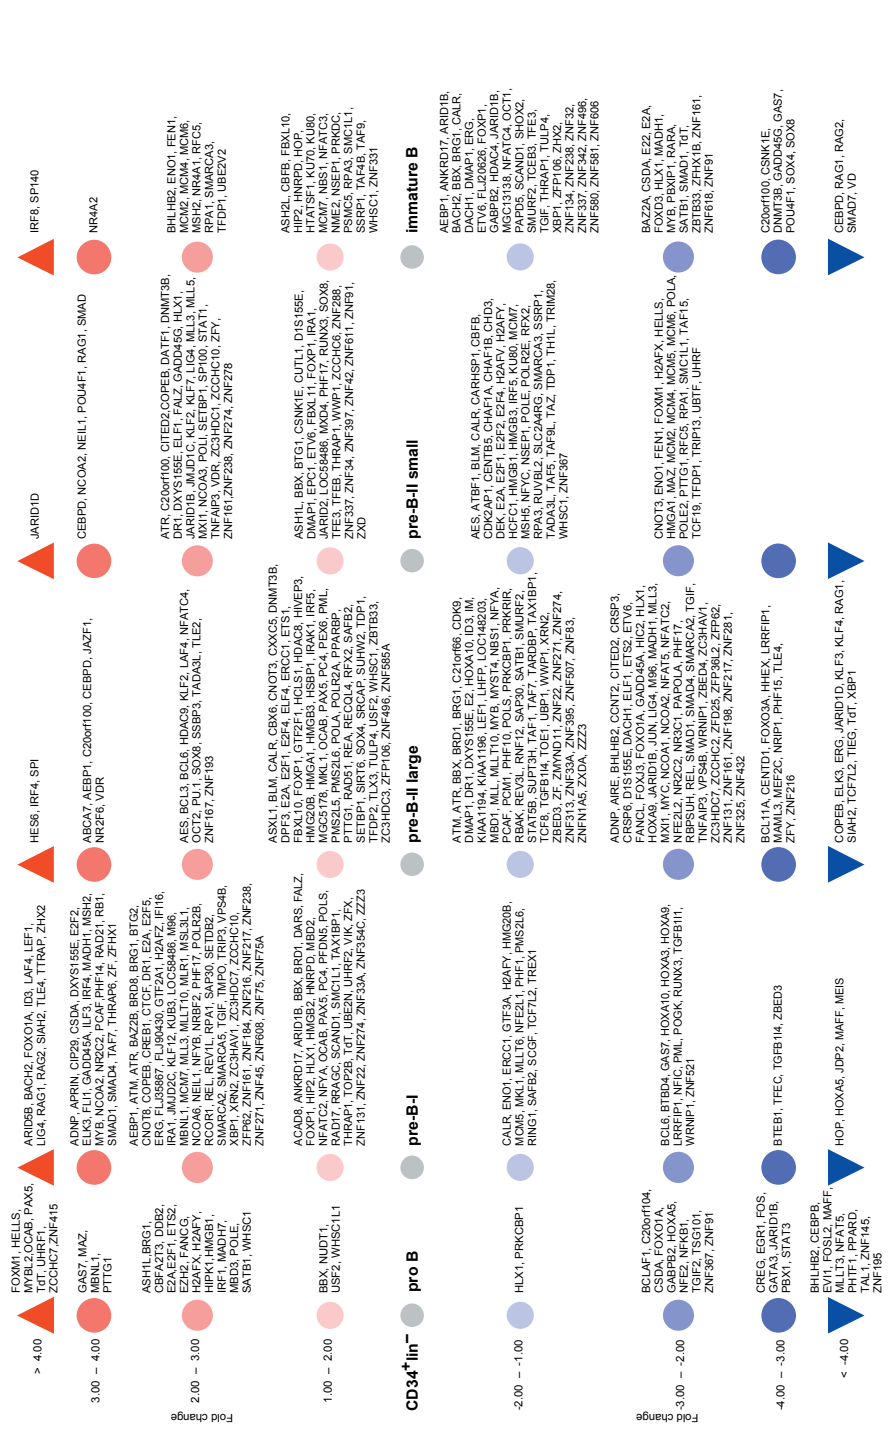

Within the remaining set of genes, a selection of 16 genes was made based on an earlier suggested role of their protein products or proteins related to them in lymphoid development (shown in bold in Table I). The expression patterns of these 16 genes, and *RAG1* and *RAG2* were confirmed with RQ-PCR (Figure 8). *KLF2* was highly up-regulated in pre-B-I cells, in which *IGH* gene rearrangements were initiated, whereas *KLF4*, *COPEB* and *KLF12* were up-regulated in both pre-B-I and small pre-B-II, where *IGK/IGL* gene rearrangements were initiated. Six Ets-family members were found in the nine clusters of Table I. *ERG* was specifically up-regulated in pre-B-I cells. Furthermore, *ELK3* and *ETS2* expression levels showed peaks in both pre-B-I and small pre-B-II cells, and *ELF1*, *ETS1* and *SPIB* were not up-regulated before the pre-B-II large stage. Four POU-domain proteins were found to be up-regulated in precursor-B cells undergoing complete V to (D)J gene rearrangements. *OCT1* was highly expressed in both pre-B-I and small pre-B-II cells, whereas *OCAB*, *OCT2* and *POU4F1* were up-regulated specifically in small pre-B-II cells. Not only *EZH2* and *BRG1*, but also transcripts of the chromatin-remodeling factor *SMARCA5* were differentially expressed with peaks in pre-B-I and small pre-B-II cells. The κ B DNA binding and recognition component *HIVEP3* is a member of the ZAS family and was found to be up-regulated in small pre-B-II cells.

In summary, a selection was made within the 5,365 significant probe sets for genes that encode transcriptional regulators. By relating their gene expression profiles to the rearrangement status of the precursor-B-cell subsets, it was possible to identify 16 novel genes that are likely to be involved in initiation and regulation of Ig gene rearrangements within the large set of differentially expressed probe sets.

DISCUSSION

In this study, for the first time cells representing the five main stages of precursor-B-cell differentiation were isolated from human BM, and were completely analyzed at the DNA level for *IGH*, *IGK* and *IGL* gene rearrangements and at the RNA level for genome-wide gene expression profiles. Incomplete D_H-J_H rearrangements were initiated in pro-B cells, whereas V_H-D_JH rearrangements were initiated in pre-B-I cells. Large cycling pre-B cells were selected for in-frame V_H-D_JH rearrangements and small pre-B-II cells initiated *IGK/IGL* gene rearrangements. Finally, immature B cells contained in-frame *IGK/IGL* gene rearrangements indicating that they had undergone positive selection for the presence of productive rearrangements that result in membrane expression of a complete BCR (summarized in Figure 8).

Incomplete *IGH* rearrangements were already abundantly present in pro-B cells, while *RAG1* and *RAG2* expression levels were hardly up-regulated (Figure 6B and Figure 8B). These data suggest that D_H-J_H rearrangements can be initiated with much lower levels of

RAG1/RAG2 than complete V_H -DJ H and *IGK/IGL* rearrangements. In contrast to human pro-B cells, murine CD19⁻ pro-B cells have germline *IGH* alleles,⁴³ most likely because different phenotypic markers have been used for their isolation. Complete V_H to DJ H rearrangements started in CD19⁺ pre-B-I cells. This is in line with up-regulated *PAX5* expression, which is critical for the initiation of complete *IGH* gene rearrangements and for the expression of CD19.⁴⁴

Rearrangements of the three types of *IGK/IGL* gene rearrangements, V_K -J K , K δ e and V_λ -J λ , were all initiated massively in small pre-B-II cells. Apparently, the current markers are not sufficient to separate precursor-B cells according to these three consecutive *IGK/IGL* rearrangement steps. Low levels of *IGK/IGL* gene rearrangements were present in pre-B-I and large pre-B-II cells. The average size of the V_K -J K junctional regions was larger in pre-B-I and large pre-B-II cells than in pre-B-II small cells (Figure 5B), indicating more N-nucleotide addition. This was in line with the higher *TdT* expression in pre-B-I cells than in large pre-B-II cells. We suggest that the low levels of V_K -J K rearrangements found before the pre-B-II small stage indicate early opening of the *IGK* locus before down-regulation of TdT. Interestingly, this phenomenon was not clearly found for *IGL* gene rearrangements.

The amount of K δ e and V_λ -J λ rearrangements in mature Ig κ ⁺ B cells was low compared with mature Ig λ ⁺ B cells, whereas V_K -J K was high in both. This confirms the hierarchical order that has been found in previous studies;^{31, 45} K δ e and V_λ -J λ rearrangements are only induced after V_K -J K rearrangements.

Correlating the Ig gene rearrangement status to the genome-wide gene expression profiles of all five precursor-B-cell subsets enabled us to study the networks of genes involved in the initiation of different types of Ig gene rearrangements. The expression of *RAG1* and *RAG2* showed peaks in pre-B-I and small pre-B-II cells, which correlated well with the initiation of complete *IGH* and *IGK/IGL* rearrangements. Interestingly, *LIG4* was the only member of the NHEJ dsDNA break repair machinery that was also up-regulated in these stages.

In addition to *RAG1* and *RAG2*, apparently also higher levels of *LIG4* are required for V(D)J recombination.

The use of mouse models has contributed enormously to the understanding of lymphocyte differentiation. However, it is still unclear which factors determine the hierarchical order of Ig gene rearrangements. In this study, a selection was made within the differentially expressed genes that regulate transcription to identify the networks of factors involved in the process of V(D)J recombination. The E2A, EBF and E2-2 transcription factors are known to be involved in the initiation of V(D)J recombination on the *IGH* locus.⁸⁻¹⁰ Transcripts encoding these proteins were directly up-regulated in the pro-B-cell stage that contains abundant DJ H -J H rearrangements. Furthermore, pro-B cells showed up-regulated expression of genes encoding EZH2 and SMARCA4, which modify the chromatin structure and thereby make the *IGH* locus accessible for V(D)J recombination.^{21, 22}

PAX5 is required for V_H -DJ H rearrangements,¹¹ and it was found to be strongly up-regulated in pre-B-I. Furthermore, *RAG1*, *RAG2*, *HMGB1*, *HMGB2*, *LIG4* and *TdT* transcripts were strongly up-regulated in pre-B-I cells. This could indicate that higher levels of the recombinase machinery are needed for initiation of V_H to DJ H gene rearrangements. In mice, IL-7R signaling induces V_H -DJ H rearrangements via STAT5 activation.⁴⁶ *STAT5B* gene expression was indeed up-regulated in human pre-B-I cells, but *IL7RA* was not expressed

^b 16 likely candidate genes involved in initiation and/or regulation of Ig gene rearrangements are shown in bold font.

Figure 8. RQ-PCR analysis confirms the correlation of 16 newly identified transcription factors with the initiation of Ig gene rearrangements in precursor-B-cell differentiation.

A. Hypothetical scheme of precursor-B-cell differentiation, summarizing the quantitative Ig gene rearrangement data. The horizontal bars represent the rearrangement of the Ig loci. The arrows show the timing of in-frame selection of V_H-DJ_H and $V_\kappa-J_\kappa / V_\lambda-J_\lambda$ after the pre-B-I and pre-B-II small cell stage, respectively; **B.** Heat map with the normalized RQ-PCR data of *RAG1* and *RAG2*, as well as the 16 candidate genes involved in initiation and/or regulation of Ig gene rearrangements. The expression patterns fully confirm the patterns observed with DNA microarray analysis with peaks in expression in one or more stages that undergo Ig gene rearrangements. Slight differences were seen for *ELF1* and *OCAB* when compared to the cluster patterns, because the cluster patterns were the averages of multiple genes expression patterns.

before the stage of large pre-B-II cells. Apparently, STAT5 might be involved in initiation of V_H - DJ_H rearrangements in man as well. However, STAT5 is probably not activated by IL7 α , but by an alternative signaling pathway.

In addition to the well-described genes, we identified a number of genes of which the expression pattern correlated with the initiation of complete *IGH* gene rearrangements. *COPEB* was significantly up-regulated in pre-B-I cells. In thymocytes, *COPEB* was found to bind to the $D\beta 1$ promoter, but in contrast to *KLF5* it did not enhance the promoter activity in murine pro-T-cell lines.⁴⁷ The up-regulation of *COPEB* in pre-B-I cells suggests that it plays a role in *IGH* gene rearrangements by binding to the enhancer in the same way *KLF5* can do this for *TCRB*, thereby opening the *IGH* locus. Furthermore, the expression of three Ets-family protein transcripts, *ETS2*, *ELK3* and *ERG*, was up-regulated specifically in pre-B-I cells. Of these, *ERG* has been found to bind to a promoter sequence in *IGH* and was able to activate a reporter construct synergistically with E2A splice variant E12,⁴⁸ making it a likely cofactor of E-box proteins for *IGH* locus opening in pre-B-I cells.

The expression of *RAG* transcripts was found to be down-regulated in large pre-B-II cells and subsequently up-regulated in small pre-B-II cells that were found to initiate *IGK/IGL* gene rearrangements. This up-regulation of the *RAG* transcripts was accompanied by an up-regulation of *IRF4*, which has been described to be involved in initiation of Ig light chain rearrangements.^{19, 20} In addition, *E2A*, *EBF*, *E2-2* and *PAX5* were highly expressed in small pre-B-II cells. *EBF* and E2A splice variant E47 have been shown to induce $V\kappa$ - $J\kappa$ rearrangements in a non-lymphoid cell line,¹⁰ and *PAX5* is required for *IGK* germline transcription.¹² *COPEB* was expressed again after down-regulation in large pre-B-II cells, suggesting it might be involved in both *IGH* and *IGK/IGL* gene rearrangements. Ets-family factors *ETS1* and *SPIB* were specifically up-regulated in small pre-B-II cells. In mice, loss of *SPIB* did not affect B-cell differentiation in BM,⁴⁹ but pro-B-cell lines derived from *PU.1/SPIB* double knockout mice showed decreased *IGL* germline transcription.⁵⁰ Rearrangements of the *IGL* locus are strictly regulated and usually occur only after the production of a functional *IGK* allele has failed. *SPIB* might act to specifically target the recombination machinery to the *IGL* locus. *HIVEP3* showed specific up-regulation in the small pre-B-II stage. Its protein product is capable of binding the κB transcriptional enhancer motif, and to the canonical RSS heptamer and nonamer.⁵¹ *HIVEP3* might function to make the RSS elements accessible for recombination, thereby creating the opportunity for many different gene segments to be recombined. Although it was found to be dispensable for precursor-B-cell differentiation,⁵² as yet, no studies have addressed a function in gene segment selection in *IGK/IGL* gene rearrangements.

With the currently available markers, it was not possible to separate the initiation of $V\kappa$ - $J\kappa$, $K\delta$ and $V\lambda$ - $J\lambda$ rearrangements, since they seem to coincide in a single stage of precursor-B-cell differentiation. However, it can be anticipated that different networks of genes regulate these three consecutive types of rearrangements, thereby creating the hierarchical order found in mature B lymphocytes.^{31, 45}

In summary, we determined the quantitative and qualitative status of all major Ig gene rearrangements in human precursor-B-cell subsets. Based on the Ig gene rearrangement patterns we divided human precursor-B-cell differentiation into five functional stages. Careful analysis of genome-wide expression profiles of these five subsets enabled us to

identify 16 novel candidate genes for initiation and regulation of *IGH* and *IGK/IGL* gene rearrangements, thereby providing insight in the mechanism of precursor-B-cell differentiation. This detailed analysis represents an excellent template for studies on oncogenic transformation in precursor-B-cell acute lymphoblastic leukemia and B-cell differentiation blocks in primary antibody deficiencies.

ABSTRACT

The immunoglobulin heavy chain (*IGH*) locus is organized in distinct regions that contain multiple variable (V_H), diversity (D_H), joining (J_H) and constant (C_H) coding elements. Spatial distance distributions were determined between 12 genomic markers that span the entire *IGH* locus. In pro-B cells, the *IGH* locus topology brought V_H segments into relative close physical proximity is on the D_H - J_H elements. Although separated by large genomic distances, the pro-B proximal and distal V_H regions were positioned at similar spatial distances from the D_H - J_H cluster. Statistical analysis showed that the pro-B *IGH* locus configuration allowed V_H regions to interact with the D_H - J_H elements with relatively high probability. Comparison of the distance distribution to simulated data described for different configurations of chromatin structure, indicated that the experimental data are most consistent with an *IGH* locus organized in rosette-like structure(s) containing bundles of loops, connected by spacers. These data indicate that the *IGH* locus displays a distinct topology, to allow long-range genomic interactions to occur with relatively high frequency.

KEY WORDS

Immunoglobulin heavy chain locus, immunoglobulin gene rearrangement, chromatin structure, spatial nuclear architecture, long-range interaction.

INTRODUCTION

It is well established that higher order chromatin organization plays a pivotal role in genome function.¹⁻³ For more than a century, the organization of chromosomes and its functional implications in eukaryotes has been extensively studied using light microscopy.^{4,5} Electron micrographs of chromosome spreads have suggested the presence of loops, with sizes of ~90 kb, that interact with the nuclear matrix and aggregate during mitosis into rosettes containing ~18 loops, resulting in ~100 rosettes per average chromosome.^{6,7} Similar rosette-like structures have been detected in interphase cells.⁸ Electron tomography has suggested another structure, a “chromonema” fiber with a diameter of 60-130 nm and agglomerations along the chromatin fiber.⁹

Initial studies have suggested that the chromatin fiber behaves like a random walk that spans the entire nucleus.¹⁰ However, the confinement to territories, chromosome arms and bands, clearly indicated the presence of spatial constraints. More recent observations demonstrated that the spatial distance depends on the genomic distance according to a power law with exponents of 0.5 below and 0.32 above a genomic separation of 4 Mb.¹¹⁻¹⁴ The constraints and the scaling behavior suggested a two level folding of the chromatin fiber, resulting in the Random-Walk/Giant-Loop (RW/GL) model.¹² In the RW/GL model, the 30 nm fiber forms 2 to 5 Mb loops that are attached to a polymer backbone. The backbone and the chromatin fiber within the loops have been proposed to follow random walk dynamics. However, distance measurements between genetic markers with genomic separations of less than 4 Mb are incompatible with the RW/GL model, whereas they are consistent with another model of chromatin structure, named the Multi-Loop-Subcompartment (MLS) model.^{3, 11} The MLS model suggests that the 30 nm fiber is folded into bundles of loops, connected by spacers of variable sizes.

Recently, computer models have been developed to evaluate and test experimental results, designs and hypotheses about the three-dimensional genome organization.^{3, 11, 15} Beyond supporting the chromatin organization into chromosome territory, arm and band domains, these simulations may reveal how the local, global and dynamic characteristics of cell nuclei are inter-connected.^{3, 15}

How genes are regulated over long distances has been a topic of intensive study. In prokaryotes, transcriptional enhancers act through looping or tracking of the intervening DNA.^{16, 17} In eukaryotic cells, chromatin compaction and looping, the presence of DNase I hypersensitive sites at regulatory elements, including transcriptional enhancers, insulators and locus control regions, influence gene expression over large genomic distances.¹⁸ The globin locus control region was shown to act long-range by associating with actively transcribing β -globin genes.^{19, 20} Other loci also have been shown to bring distant enhancer elements into proximity of promoter regions by looping, including the Th2 cytokine locus and the interferon gamma gene.^{21, 22} How these genes and regulatory elements are organized in 3D-space remains to be determined.

The murine immunoglobulin heavy chain locus (*IGH*), is organized into distinct regions that contain the variable (V_H), diversity (D_H), joining (J_H), and constant (C_H) coding elements. Eight constant regions encode the various isotypes: C_{μ} , C_{δ} , $C_{\gamma 1}$, $C_{\gamma 2a}$, $C_{\gamma 2b}$, $C_{\gamma 3}$, C_{α} and C_{ϵ} . Twelve D_H and four J_H segments are positioned immediately upstream of the C_{μ} constant

region. There are at least 134 V_H gene segments that belong to fifteen partially interspersed families.²³ The V_H, D_H and J_H coding elements are flanked by recombination signal sequences (RSSs) that act as recognition elements for the V(D)J-recombinase: RAG1 and RAG2.^{24, 25}

The *IGH* and Ig light chain loci undergo ordered rearrangement during B-lineage development.²⁶ In pro-B cells, D_H to J_H rearrangement precedes V_H to D_HJ_H joining. Once an in-frame VDJ_H joint has been generated, a pre-B-cell receptor is formed, suppressing RAG1/2 activity, and preventing continued *IGH* gene rearrangement.^{27, 28} The temporal and lineage specificity of V(D)J recombination is controlled at distinct levels, including DNA methylation, chromatin remodeling, histone acetylation, germline transcription and transcription elongation.²⁴ Fluorescence *in situ* hybridization (FISH) analysis has demonstrated that the *IGH* alleles are located in close proximity to the nuclear membrane in T-lineage cells.²⁹ In B-lineage cells, the *IGH* locus is located away from the nuclear membrane and the V_H regions undergo contraction and looping.²⁹⁻³² However, it is unclear how a large region spanning 3 Mb allows efficient joining of V_H to D_H gene segments. It seems plausible that within such a large genomic locus an underlying order facilitates this interaction.³³

To explore the 3D-architecture of the *IGH* locus, we combined 3D structure-preserving FISH with multiple probes that span the entire *IGH* locus and computer modeling to determine and analyze spatial distances between small genetic markers as a function of their genomic separation. Collectively, the data are most compatible with a topology in which the *IGH* chromatin polymer is organized in rosette-like structures, containing multiple loops, which allow long-range genomic interactions to occur with relatively high frequency.

RESULTS

High Resolution Spatial Distance Measurements between Genomic Markers in B-lineage Cells

We previously used 100-150 kb BAC probes to simultaneously visualize three distinct regions of the *IGH* locus.³² However, the resolution obtained using this approach was limited, due to the large sizes of the probes. Here we use relatively small DNA probes (10 kb) to visualize the *IGH* locus. To label 10 kb DNA segments, a direct probe labeling procedure was employed (1-4 labeled nucleotides per 100 bp; see Materials and Methods). E2A-deficient pre-pro-B cells and RAG2-deficient pro-B cells were fixed, permeabilized and hybridized with one 235 kb BAC and two 10 kb probes to visualize the *IGH* locus (Figure 1A). The fluorescent signals emitted by the 10 kb probes were clearly detectable, but the intensity varied between the different probes (Figure 1A). The *IGH* locus in E2A-deficient pre-pro-B cells is located closer to the nuclear membrane as compared to RAG-deficient pro-B cells, confirming previous observations (Figure 1B and C).²⁹

To determine the smallest measurable distance, we calculated the full width at half maximum (FWHM) of the point spread function of the optical system used in the experiments described below (400-1,800 nm range; Appendices 4 and 5). Although the resolution obtained was rather limited, measurements of considerably smaller distances were achieved using different absorption/emission spectra and correction for chromatic shifts. The average distance measured for the different combinations of the fluorochromes ranged between 35 and 47 nm,

with standard deviations of 18 and 24 nm, respectively (Appendix 6). Thus, this approach allowed us to measure spatial distances with a 3D-resolution better than 100 nm.

3D-Architecture of the *IGH* Locus

To gain insight into the topology of the *IGH* locus, we measured the spatial distances between an anchor, BAC probe RP23-201H14, and eleven 10 kb probes that span the entire locus (Figure 2A). Both pre-pro-B and pro-B cells were examined. We noted that the average distances and standard deviations were substantially higher than the smallest measurable distance (Figure 2B; Appendix 6). Consequently, this approach allowed us to accurately determine spatial distances in interphase nuclei. The distance distributions are not well described by a Gaussian distribution as expected for a random walk unaffected by tethering and confinement, but rather can be fitted as Rayleigh distributions (Figure 2B and S.J., unpublished observations). The average spatial distances separating the anchor RP23-201H14 and the markers located within the C_H region cluster (h2 and h3) increased with increasing genomic separation (Figure 2B and C). The pattern leveled off beyond the intronic enhancer in pro-B cells indicating confinement within the pre-pro-B-cell nucleus (Figure 2C). Local inversions in the pattern were observed in the region containing the *IGH* intronic enhancer and the region separating the proximal and distal V_H regions (Figure 2C). When compared to the spatial organization in pre-pro-B cells, the *IGH* locus configuration in pro-B cells showed substantial spatial contraction beyond the *IGH* intronic enhancer (Figure 2C; Table 1). The differences in compaction values between pre-pro-B and pro-B cells, were particularly striking in the distal V_H cluster (1284 versus 2059 between RP23-201H14 and h11; Table 1). Taken together, the spatial organization and compaction values indicate that the 3D-architecture of the *IGH* locus differs between pre-pro-B and pro-B cells.

Long-range Genomic Separation but Similar Spatial Distances

The data described above showed a high degree of compaction between the distal V_H and C_H regions (Figure 2C). Because during B-cell differentiation V_H gene segments rearrange to D_HJ_H gene segments, we measured the spatial distances separating the V_H regions from the D_HJ_H cluster (Figure 3A). The average spatial distances between the D_HJ_H elements and the proximal V_H regions were similar for pre-pro-B and pro-B cells (Figure 3B-C and Table 1). In contrast, the spatial distances separating the distal V_H and D_HJ_H regions were substantially larger in pre-pro-B cells as compared to pro-B cells (Figure 3C). The degree of compaction was particularly high beyond the proximal V_H region in pro-B cells (Table 1). Notably, in pro-B cells the spatial distances separating the proximal and distal V_H regions from the D_HJ_H cluster were similar (Figure 3C). On the other hand, the spatial distances separating the D_HJ_H elements from the C_H regions were larger in pro-B cells as compared to pre-pro-B cells (Figure 3C). These data suggest that upon commitment to the B-cell lineage, the *IGH* locus is remodeled to allow the proximal and distal V_H regions equal access to the D_HJ_H elements.

Long-range Interaction Probability and V_H to D_HJ_H Joining

The V(D)J recombination process requires that the V_H and D_HJ_H segments are mobile, thus allowing them to interact with each other with detectable frequency. What are the probabilities of such encounters in pre-pro-B versus pro-B cells? The frequency by which V_H regions are

n refers to number of nuclei analyzed; <x> indicates average spatial distance; SD indicates standard deviation; SE refers to standard error;

The average DNA compaction based on the linear contour length of 340 nm for 1.0 kbp was calculated from: $\frac{\text{genomic length [kbp]} \cdot 340 \text{ [nm/kb]}}{\text{spatial distance [nm]}}$

positioned in close proximity to D_{HJH} elements, can be derived from the cumulative distance distributions (Figure 3B). The distance distributions for the proximal V_H regions were similar for pre-pro-B cells and pro-B cells (Figure 3B). In contrast, the cumulative distance distributions for distal V_H regions (h4-h10; h4-h11), differed substantially between pre-pro-B and pro-B cells (Figure 3B). Specifically, the probability that a distal V_H region was located within relative close proximity (sub 100-200 nm range) to the D_{HJH} elements was substantially lower in pre-pro-B cells as compared to pro-B cells (Figure 3B).

To study the probabilities that V_H regions are located in relative close proximity (100-200 nm) to the D_{HJH} cluster, the cumulative distance distributions separating the V_H from the D_{HJH} elements were plotted (Figure 4). In pre-pro-B cells, the probabilities of V_H regions to interact with D_{HJH} elements correlated well with increasing genomic separation (Figure 4A). In contrast, in pro-B cells the probability distribution was clustered at low spatial distances (sub 350 nm) for the majority of V_H regions (Figure 4B). Collectively, these data show that in pro-B cells, the probabilities of V_H regions to interact with the D_{HJH} elements are similar, regardless of their genomic separation.

***IGH* Locus Configuration and the Random Walk Model**

Previous observations indicated that the chromatin fiber in budding yeast (*Saccharomyces cerevisiae*) can be described as a worm-like chain.³⁴ Our analysis of the average spatial distances, the locus dynamics and interaction probabilities suggest that the *IGH* chromatin fiber configuration is incompatible with that of a free worm-like chain. To determine whether there is any condition under which the *IGH* 3D-architecture can be explained by random walk behavior, the experimental spatial distances were compared to the Kratky-Porod description of a worm-like chain.³⁵ In this approach, only the flexibility of the chromatin fiber, the persistence length L , and the density of the chromatin fiber c determine, for a specific genomic separation, the average theoretical spatial distance (see Material and Methods for details). No reasonable values could be found for either the pre-pro-B or the pro-B cells, using different values for both parameters (Figure 5A and B). A least square optimization analysis also showed values with $L = 0.85$ nm and $c = 5.9$ bp/nm, respectively, that are not compatible with the physical properties of the chromatin fiber (S.J., unpublished observations). These data indicate that unlike budding yeast chromatin, the spectrum of *IGH* conformations cannot be described in terms of a worm-like chain.

Chromatin Fiber Statistics in *Saccharomyces cerevisiae* and B-lineage Cells

In budding yeast, long-range genomic interactions have not been reported. In contrast, vertebrate organisms have the ability to modulate gene expression from regulatory elements that are separated by large genomic distances.¹⁸ Why is it that DNA segments, separated by large genomic distances in budding yeast, are not able to encounter each other, whereas in multicellular organisms enhancers and locus control regions physically interact with promoter regions with detectable frequency?^{19, 20} Our observations raise the possibility that it is the distinct chromatin topology in mammalian cells that allows genomic elements to interact long-range with relatively high probability. To address this possibility, we directly compared the theoretical probabilities by which DNA elements interact in budding yeast, modeled as a 3D random walk, to our experimental values obtained from B-lineage cells.

Figure 3. Altered *IGH* locus Topology in Pro-B cells Brings Distal V_H Regions and D_HJ_H and Enhancer Elements in Close Proximity.

A. Strategy to generate a physical map of the *IGH* locus using a region containing the D_HJ_H elements and the intronic enhancer as an anchor. **B.** Frequency plots showing the distribution of spatial distances for each genomic marker from the D_HJ_H cluster in pre-pro-B cells and pro-B cells. X-axis shows spatial distances in μm . Y-axis indicates frequency monitored for each of the spatial distances. Distances were corrected for chromatic shifts. **C.** Average spatial distances were plotted as a function of genomic separation for each of the probes. Mean distances are indicated \pm standard error. The dotted lines only indicate connectivity, but the exact path between two data points is not known.

Cumulative frequency distributions for yeast chromatin were determined for different persistence lengths (see Materials and Methods for details). For the shortest genomic separation (h4-h5) and using 50 nm as a persistence length value, the theoretical distance distribution for a random walk approaches that of pre-pro-B and pro-B cells (Figure 5C-F). However, for larger genomic separations, the cumulative frequency distributions, using the same range of values for persistence lengths, do not compare well with those obtained from the experimental data (Figure 5C-F). Thus, it is the *IGH* locus topology in pro-B cells that allows genomic and regulatory elements to encounter one another long-range with relatively high frequency.

Computer Modeling of Chromatin Structure and Comparison of Simulated to Experimental Data

To determine the 3D-architecture of the *IGH* locus in more detail, computer simulations were performed using Monte Carlo and Brownian Dynamics methods (Figure 6A and B).³ The RW/GL and MLS models were used as starting configurations. The 30 nm fiber was modeled as an elastic polymer chain. The persistence length L_p and the density c of the chromatin fiber were based on a previous consensus comparison and integration of experimental data.³ We note that variations in persistence length and chromatin density do not have a large influence on this analysis. Different loop and spacer sizes were used at $\sim 5,000$ bp resolution, which is >19 times smaller than the smallest genomic separation investigated in this study. The different architecture and morphology of chromatin structure that these models

Figure 4. Probabilities for Proximal and Distal V_H Regions to Interact with D_HJ_H Elements are Similar in Pro-B Cells Regardless of Genomic Separation.

A, B. Probabilities of proximal and distal V_H regions to interact with D_HJ_H elements in pre-pro-B cells and pro-B cells. Cumulative frequencies were obtained by accumulating the frequency values corresponding to the spatial distances in intervals of 100 nm using the D_HJ_H elements (probe h4) as an anchor. The dotted line indicating the spatial distance below which the cumulative frequencies cluster in pro-B cells.

show provide a qualitative idea about the outcome concerning the average spatial distances, the locus dynamics and interaction probabilities (Figure 5A).

There are now two challenges to be met by comparing the experimental with the simulated data:

- (1) Spatial distances depend strongly on the probe placement and whether the 3D-architecture is fixed or variable relative to the DNA sequence (i.e. whether loops with a defined rigid/ "covalent" loop base exist or not);
- (2) *A priori* neither is the coverage of the *IGH* locus with genomic markers high enough, nor do the results of the quantitative measurements indicate the location of the experimental probes or the variability of the underlying chromatin architecture.

Therefore, the best approach is to assume both and to place the virtual markers in a position-independent and position-dependent manner on simulated chromatin architecture. Then the average is taken over several states of the same architecture. For position-dependent placement, the virtual anchor point was placed at the base of a loop (Figure 6D). For the position-independent placing of the virtual markers, the anchor point was placed randomly within the chain of segments. This sort of unconstrained measurement also reflects experimental imperfections. Vice versa these two types of analysis also reflect the variability of genome architecture: Changes in the architecture will be reflected by changing the position of the marker with respect to the architecture! This is obvious e.g. for virtual average spatial distances (Figure 6C-E) or for virtual distance distributions, i.e. interaction probabilities (Figure 6F).

When first considering position-independent achieved virtual average spatial distances, it is immediately apparent that already above 250 kb the experimental data do not agree with RW/GL models, even with loops as small as 252 kb (Figure 6C and G). These data are consistent with the analysis described above that excluded random walk behavior. Instead, the experimental data are most consistent with that described for an MLS model for both pre-pro-B and pro-B cells. Estimated from the genomic separations below 500 kb, the loop sizes range from around 80 to 150 kb (for more detailed analysis of loop size variation see Knoch³). The virtual spatial distance behavior also supports the observation that there might be possible agreements with a wormlike chain for very small genomic separations. Thus, within a loop, the chromatin could behave like a random walk. However, the smallest genomic separation we studied was 94 kb. Therefore, we could not perform a reasonable analytical analysis with low influence of the chromatin folding to determine the persistence length and the internal chromatin fiber density. Spacer sizes of 60 to 70 kb show the best

Figure 5. (facing page) The *IGH* Chromatin Topology cannot be Described as a Worm-like Chain.

A. Using the Kratky-Porod equation,³⁵ spatial distances were plotted as a function of genomic separation for different chromatin densities, but with a constant persistence length. Spatial distances were plotted as a function of genomic separation for a worm-like chain with a persistence length of 200 nm and a range of chromatin densities (100-10,000 bp/nm). **B.** Using the Kratky-Porod equation, spatial distances were plotted as a function of genomic separation with a range in persistence length of 50-200 nm and a constant chromatin density of 130 bp/nm. **C-F.** Probabilities of V_H regions to interact with D_HJ_H elements in pre-pro-B and pro-B cells compared to theoretical probabilities of a 3D random walk. Cumulative frequencies were obtained by accumulating the frequency values corresponding to the spatial distances in intervals of 100 nm using the D_HJ_H elements (probe h4) as an anchor. Cumulative frequency distributions for the random walk were determined for different persistence lengths (see Materials and Methods).

agreements for genomic separations up to ~ 1.0 Mb. For larger separations, the virtual spatial distances would correspond to much smaller spacers for both pre-pro-B and pro-B cells and independent of the experimental anchor point. It now becomes obvious that the plateau behavior in pro-B cells, for genomic separations above 0.5 to 1.0 Mb is not arbitrary but distinct: Thus, the entire *IGH* locus in pro-B cells might span one single loop cluster. However, it is conceivable that two or more loop clusters are present, connected by relatively small sized spacers. The virtual markers placed in a position-dependent way in fixed chromatin architecture clarify this (Figure 6E). Notably, this domain contains the distal V_H regions and shows distinct conformations in pre-pro-B and pro-B cells.

The computer modeling also confirms that the local inversions and peaks as well as the functional differences mentioned above are relevant and can be indeed interpreted as rearrangement of the locus architecture. These interpretations are even more striking when considering the *IGH* locus dynamics: The interaction probability between V_H and $DHJH$ gene segments is reflected by changing the position-dependent placed makers as function

Figure 6. (facing page) Comparison and Evaluation of Spatial Distances Between Genomic Markers in the Murine *IGH* Locus by Computer Simulations.

A. Simulation of decondensation of a metaphase-like chromosome (α) consisting of stacked rosettes linked by a chromatin loop into thermodynamically equilibrated interphase configurations. γ depicts a Multi-Loop-Subcompartment (MLS) organization with 126 kb rosettes and 126 kb spacers. β depicts a Random-Walk/Giant-Loop (RW/GL) organization with 5 Mb loops and 378 kb spacers, whereas the RW/GL organization in δ consists of 126 kb loops and 63 kb spacers. The fiber diameter was set at 30 nm and adjacent loops or rosettes are shown in red and green. B. Diagrams of hypothetical chromatin organization according to the RW/GL model and the MLS model. The RW/GL model is depicted with large loops attached to a non-DNA backbone (α), and with large loops simulated with a chromatin spacer in-between (β). The MLS model shows ~ 100 kb loops that form rosettes, which are connected by a chromatin spacer. C. Spatial distances of the experimental data and position dependent distance simulations of the RW/GL and MLS models with various parameters plotted as a function of genomic separation. The experimental data is plotted as independent data points, whereas the average of the distance distribution for the various models are depicted as solid lines. Nomenclature for the different models: nomenclature: (loop size [kb])-(linker size [kb])-(modelname). D. Schematic representation of two rosettes and a spacer according to the MLS model. For position-independent spatial distances, markers with a given genetic separation are placed randomly with respect to the chromatin topology reflecting also a dynamic chromatin organization, although with certain loop and spacer properties. In contrast, for position-dependent spatial distances, distances are measured from one marker to other markers reflecting a static chromatin organization (1-10). Thus, strong dependencies occur for position-dependent spatial distances if an ensemble of genomic markers is shifted through given chromatin topology (x^1, x^2, x^3). E. The comparison between simulated position-dependent and position-independent spatial distances reveal in the first case the detailed loop structure and transition into a spacer and the next loop or rosette (see model legend in C). F. The distributions of position-dependent spatial distances of a genetic marker pair with 252 kb genetic distance shifted through a rosette and into a spacer of an 126-126-MLS model reveals the dependence on the marker position. G. Spatial distances of the experimental data and position-dependent simulations of the RW/GL and MLS models with various parameters plotted as a function of genomic separation (see model legend in C).

of their location, thus completely supporting the interpretation from above (Figure 6F). Consequently, analysis of the 3D chromatin architecture in the *IGH* locus by comparison to structural computer models reveals that an organization into at least one or two rosette-like clusters of small loops connected by spacers (Figure 7). Taken together, the experimental data are most consistent with a MLS configuration in which the *IGH* locus is organized in 1-2 Mb subcompartments, which contain multiple loops, separated by spacers.

Figure 7. Hypothetical diagram of *IGH* rosettes with a sizeable spacer (in green).

We hypothesize that pre-pro-B cells have a stretched spacer (A), whereas the spacer in-between the *IGH* rosettes is contracted in pro-B cells (B), thereby repositioning the distal V_H gene segments within the same spatial distance from the D_HJ_H cluster as the proximal V_H gene segments.

DISCUSSION

The DNA sequences of a wide variety of genomes have been characterized in substantial detail. How the genome is tangled in 3D-space, however, is largely unknown. Here we used the *IGH* locus as a model system to examine the spectrum of structural conformations in interphase nuclei. The *IGH* locus is of interest and suitable for these studies for the following reasons: (1) The *IGH* locus is large, spanning over 3 Mb of genomic sequence, making it amenable to physical scrutiny; (2) The *IGH* locus contains multiple well-characterized coding and non-coding elements; (3) The *IGH* regulatory elements are well characterized; (4) The *IGH* locus undergoes genomic rearrangement between distant elements in a temporal and lineage-specific fashion. Here we demonstrate that the *IGH* locus, while highly dynamic, is structured and how the *IGH* locus configuration is altered to affects its function.

High-resolution 3D Structure-preserving Fluorescence Microscopy and *IGH* Locus Topology

In the studies described here we use spectral precision distance fluorescence microscopy to determine spatial distances between genetic markers. Measuring the point spread function and chromatic shifts, we demonstrate that fluorescence microscopy using two fluorochrome-labeled probes, unlike single labeled probes, allows a resolution (less than 50 nm) that is well below the average spatial distances and standard deviations recorded in this study. Consequently, spectral precision distance fluorescence microscopy allows accurate spatial measurements between probes that are labeled with different fluorochromes to determine the *IGH* locus topology.

We used a structure-preserving fixation and permeabilization protocol to prepare nuclei for spectral precision distance fluorescence microscopy. However, it remains to be determined to what degree our experimental design affects *IGH* locus spatial organization. Although the cells were fixed with paraformaldehyde in an isotonic environment, we cannot exclude the possibility that shifting of the *IGH* fiber may have occurred during the fixation procedure. Furthermore, we cannot exclude the possibility that DNA denaturation leads to distortions in *IGH* topology. In *Saccharomyces cerevisiae*, both 3D structure-preserving fluorescence microscopy and live-imaging of fluorescently labeled proteins targeted to the chromatin fiber have been used to determine spatial distances.³⁴ Direct comparison of these two approaches, has indicated that structure-preserving fixation and denaturation conditions do not substantially alter spatial distances.³⁴ Based on these results, it seems unlikely that the fixation and denaturation conditions used in this analysis substantially interfere with the spatial organization of the *IGH* fiber. Nevertheless, we note that ultimately it will be important to target fluorescently labeled proteins to the *IGH* chromatin fiber, to examine the *IGH* locus conformation and dynamics in live B cells.

***IGH* Locus Topology**

Previous studies have established that the *IGH* locus shows long-range complexity in both B-and T-lineage cells.²⁹⁻³² However, it has remained unclear whether the *IGH* locus configuration can be described as a random walk or is specifically structured to facilitate long-range interactions. As a first approach to answer this question, we performed distance

measurements between multiple regions within the *IGH* locus, and compared the obtained experimental data to different models of polymer structure. The data are not at all compatible with an *IGH* topology described as a 3D random walk/worm-like chain. Rather, comparison of the experimental observations with that of simulated data suggests that the *IGH* locus is structured into subcompartments that contain bundles of loops (multi-loop subcompartments). While the overall topology of the *IGH* locus is most consistent with that of the MLS model, there are substantial differences between the *IGH* configurations in pre-pro-B and pro-B cells. The best agreement for the *IGH* configuration in pre-pro-B cells is obtained when we assume 126 kb size loops that are organized as rosettes (1-2 Mb) separated by spacers of 65-126 kb. The *IGH* topology in pro-B cells differs from pre-pro-B cells beyond a region separating the proximal and distal V_H regions (Figure 6). How is the *IGH* locus organized in pro-B cells? It is plausible that in pro-B cells, the proximal and distal V_H regions are localized in a single rosette. However, we favor a configuration in which multiple rosettes, separated by spacers, comprise the *IGH* locus in both pre-pro-B and pro-B cells (Figure 7). We note that shortening the spacer is an attractive mechanism to decrease the spatial distance separating compartments that contain D_HJ_H elements and distal V_H regions (Figures 3C and 7). A candidate for modulating the spacer size is Pax5, which has been demonstrated to promote *IGH* locus compaction in pro-B cells.³⁰

Rosette formation of the *IGH* Fiber

The organization of the *IGH* locus in clusters of loops raises the question how these loops are formed. Previous studies have suggested that the *IGH* fiber is attached to the nuclear matrix, a component that is resistant to salt extraction and DNase I digestion.³⁶ In principle, the loops may attach to the matrix associating regions (MARs) that have been identified flanking the *IGH* intronic enhancer and flanking the majority of V_H gene segments.^{37, 38} The MAR sequences present within the *IGH* locus are not critical for V_H to D_HJ_H gene rearrangement.³⁹ Still, it is conceivable that deleting a single MAR does not substantially interfere with overall *IGH* topology, and it will be of interest to examine the *IGH* locus topology in pro-B cells deficient for MAR-binding proteins such as Cux/CDP, Bright and SATB2.

Does the comparison of experimental and simulated data imply that the *IGH* fiber is organized into rosettes consisting of 126 kb loops? We consider this highly unlikely. Rather, we suggest that loop size within the chromatin territories varies substantially and might be regulated, at least in part, by factors that interact with specific DNA sequences localized at the “bases” of loops. These factors could also determine the spacing between the loops within the subcompartments. The MLS model suggests that a bundle of loops forms a complete rosette. However, we emphasize that the folding of loops into higher order structures will not necessarily lead to the formation of complete rosettes. Rather, it is conceivable that rosettes only partially form and that the degree of rosette formation will depend on the presence of DNA sequences to which “loop-base” interacting factors bind. We also suggest that loops are not stable configurations, but fold and unfold continuously, regulated by transient interactions that involve “loop-base” interacting proteins.

Long-range Genomic Separation and Enhancer Function

Previous studies have established that enhancer elements act long-range in terms of genomic distance and independent of orientation in vertebrate organisms.¹⁸ The *IGH* intronic

enhancer plays a critical role in regulating V_H to D_HJ_H gene rearrangements. Whereas distal and proximal V_H to D_HJ_H gene rearrangements are severely perturbed in mice that carry deletions of the intronic enhancer, D_H to J_H gene rearrangements are only modestly impaired.⁴⁰ Although still to be proven, we presuppose that the *IGH* intronic enhancer modulates accessibility of the V_H gene segments to the recombination machinery. This implies that the enhancer acts over large genomic distances (up to 2 Mb). How does the *IGH* intronic enhancer act over such large genomic distances to modulate V_H to D_HJ_H gene rearrangement? We propose that the *IGH* locus is organized into bundles of loops, resulting in 1 Mb subcompartments. This topology allows regulatory elements, e.g. promoters and enhancers, separated by large genomic distances, to interact at close spatial distances.

Unlike mammalian cells, long-range genomic interactions in budding yeast have not been described. Why do enhancer elements have the ability to activate transcription from DNA elements that are separated by large genomic distances in the majority of eukaryotic organisms but not in budding yeast? We show here that if the *IGH* configuration is organized as a simple random walk, as observed for chromosomal DNA in budding yeast, the probability by which the majority of the proximal and all of the distal V_H region promoters find the intronic enhancer would be overwhelmingly close to zero. Thus, our data imply that the statistical properties of the yeast chromatin fiber are incompatible with long-range genomic encounters (>250 kb). Furthermore, they suggest that the physical properties and structural organization of the *IGH* locus polymer in pro-B cells are the underlying mechanisms that allow DNA elements to act long range in genomic terms.

V_H to D_HJ_H Recombination and Long-range Interactions

The V_H families have been categorized into proximal and distal classes, based on their genomic separation from the D_HJ_H cluster. In general, no correlation exists between V_H region usage and genomic location.⁴¹⁻⁴³ We found that the cumulative distance distributions indicate that distal and proximal V_H regions have similar probabilities in finding the D_HJ_H cluster in pro-B cells. Thus, these data explain previous observations indicating that V_H regions scattered throughout the *IGH* locus rearrange with frequencies that seem independent of genomic location. We did observe a relatively high probability for V_H regions located in immediate proximity of the D_H region to encounter D_HJ_H elements (Figures 3B and 4). These V_H gene segments are more frequently found in V_H to D_HJ_H rearrangements.^{44, 45} It is conceivable that these V_H regions are located within the same loop or possibly spacer as the D_HJ_H elements.

Statistical analysis indicates that the probabilities of distal V_H regions to encounter the D_HJ_H cluster in pre-pro-B cells are low when compared to pro-B cells. Thus, upon commitment to the B-cell lineage, the spectrum of *IGH* conformations is altered, to allow V_H regions to associate with D_HJ_H elements with higher frequency. What is the underlying mechanism that allows distal V_H regions, separated by 1-2 Mb of genomic distance from the D_HJ_H cluster, to rearrange with similar frequencies as V_H regions localized in closer proximity? We speculate that the D_H , J_H and C_H elements and the *IGH* intronic enhancer are packed into one subcompartment. The proximal and distal V_H regions are organized in two distinct chromatin territories, each comprised of bundles of loops and spanning large genomic distances. In pro-B cells, both territories are positioned at equal distances from the D_HJ_H elements, and consequently have the ability to interact with equal probabilities with D_HJ_H elements (Figure 7).

Conclusion

The data described in this study provide insight into the structural organization of the *IGH* locus. It is unlikely that the topology described here is restricted to that of the *IGH* locus, and therefore it will be of interest to examine whether other genetic loci also show this configuration. Our observations also provide physical insight into how DNA elements that are separated by large genomic distances, encounter each other. It demonstrates that the chromatin topology determines the probability of these encounters and it will be of interest to examine how chromatin topology has evolved in multicellular organisms to allow high-density packing and promote long-range genomic interactions.

EXPERIMENTAL PROCEDURES

Mice and Cell Culture

All mice used were maintained in a C57BL/6 background. Rag2^{-/-} pro-B cells and E2A^{-/-} hematopoietic progenitors were isolated and grown as described previously.^{32, 46} Two cell types were used in these studies: (1) An E2A-deficient hematopoietic progenitor cell line was examined, because these cells are arrested at the pre-pro-B cell stage and have not yet committed to the B-cell lineage;⁴⁶ (2) RAG2-deficient pro-B cells were chosen, because they are committed to the B-cell lineage but unlike wild-type pro-B cells they carry the *IGH* locus in germline configuration.⁴⁷ Since the genomic organization of the *IGH* locus differs substantially between C57Bl/6 and 129 mice strains, genomic DNA was isolated from E2A-deficient pre-pro-B and RAG2-deficient pro-B cells to determine their origins. PCR analysis confirmed that both cell types were derived from C57Bl/6 mice (R.R., data not shown). Thus, the genomic distances calculated in the experiments described in this study were derived from the C57Bl/6 genome.

Design, Cloning and Labeling of 10 kb Probes

A percentage identity plot of the *IGH* locus was generated using the PipMaker tool.⁴⁸ Eleven unique 10 kb DNA segments, i.e. regions that were not duplicated within the *IGH* locus and showing minimal genomic repeats, were identified on the generated percentage identity plot. Long-range PCR (Eppendorf) using newly designed primers was used to amplify the selected 10 kb stretches. The obtained PCR products were cloned into the pGEMTeasy vector system (Promega), and the identities of individual clones were confirmed by restriction mapping and DNA sequencing. One µg of DNA was labeled with aminoallyl-dUTP (ARES labeling kits, Invitrogen) by nick-translation (Roche) in a 20 µl reaction for 3 hours and 45 minutes. The nick-translated products were size selected on a 0.6 % agarose gel and 10-500 bp fragments were purified using a Qiagen gel extraction kits. Aminoallyl-modified DNA was fluorescently labeled with succinimidyl ester derivatives of Alexa fluorochromes (Alexa-488, -594 or -647).

High-resolution 3D Structure-preserving FISH

Approximately 40 µl of a 1 x 10⁶ cells/ml suspension of cells was directly attached to coverslips. The cells were fixed in 4 % paraformaldehyde for 10 min at room temperature

(RT) and subsequently incubated with 0.1M Tris-Cl pH7.2 for 10 min at RT and washed with PBS. The cells were permeabilized for 10 min at RT with PBS plus 0.1 % triton X-100 plus 0.1 % saponin (WBI) and then incubated for 20 min in 20 % glycerol in PBS solution. Subsequently, the coverslips were immersed in liquid nitrogen and thawed for three consecutive times. The cells were washed once with PBS and incubated at 37°C in PBS plus 5 % bovine serum albumin and 0.1% Triton X-100 (BBI). The cells were subsequently incubated for 5 min in the presence of 0.1M Tris-Cl pH7.2 and then washed in phosphate buffered saline. The coverslips were then treated for 30 minutes with a 0.1 N HCl solution at room temperature, washed once in PBS, and incubated with 0.1 µg/ml DNase-free RNase in BB1 for 1 hour at 37°C. The cells were washed once with PBS, incubated in PBS supplemented with 0.5 % triton X-100, 0.5 % saponin solution for 30 minutes at room temperature, and washed once with PBS. Nuclear DNA was denatured by incubating coverslips for 2 minutes and 30 seconds at 73°C in 2x SSC, 70 % formamide solution, followed by an incubation of 1 minute in 2x SSC plus 50 % formamide. Excess liquid was removed and 10 µl of hybridization cocktail was added to each of the coverslips. The coverslips were mounted, sealed with rubber-cement, and incubated overnight at 37°C. The hybridization solution contained 400 ng of each labeled probe, 4 µg of mouse C₀t DNA, 1 µg of sheared salmon-sperm DNA dissolved in 50 % formamide, 2x SSC and 10 % dextran sulfate. The probes were denatured at 70°C for 5 minutes and chilled on ice prior to incubation with the cells on the coverslips. The following day, the coverslips were removed and washed once with 2x SSC and 50 % formamide for 15 minutes, and 3 times with 2x SSC for 5 minutes at 37°C. The coverslips were subsequently incubated in 2x SSC, 3 % BSA, 0.1 % Tween-20 (BB2) at room temperature for 30 minutes. The coverslips were then washed twice for 10 minutes in 2x SSC plus 0.1 % Tween-20 and once in PBS at room temperature. Excess PBS was removed and the coverslips were mounted on slides.

Image Acquisitions, Distance Calculations, Calibration and Statistics

Images were captured with a DeltaVision deconvolution microscope system (Applied Precision, Inc.) located at the UCSD cancer center microscope facility. Using a 100x (NA 1.4) lens, images of approximately 40 serial optical sections spaced by 0.2 µm were acquired from experiments involving BAC DNA probes only, and 80 serial optical sections spaced by 0.1 µm were acquired from experiments involving 10 kb DNA probes. The data sets were deconvolved and optical sections merged to produce 3D images using SoftWorx software (Applied Precision, Inc) on a Silicon Graphics Octane workstation. The 3D-coordinates of the centre of mass of each probe were obtained to calculate the distances separating each probe according to the equation

$$\sqrt{(X_a - X_b)^2 + (Y_a - Y_b)^2 + (Z_a - Z_b)^2}$$

where X, Y, and Z are the coordinates of object a or b.

To determine the smallest measurable distance by spectral precision distance fluorescence microscopy, the “resolution equivalent” (RE) was determined. Both the point spread function as well as chromatic shifts were determined. The PSF with its full width at half the maximum (FWHM) of the microscope was measured with fluorescent tetraspeck beads (Invitrogen, 0.2 µm) at 0.1 µm intervals.

To exclude positional shifts of signals representing probes labeled with different fluorochromes, the distance measurements were corrected for chromatic shifts. To measure chromatic shifts, 0.2 μm tetraspeck beads were used. Each bead was uniformly stained with a mixture of fluorescent dyes that emit in the blue, green, orange and dark red wavelengths. The coordinates of the center of the beads were determined for each of the colors that were used in the FISH analysis. For any two colors, the average separation between the coordinates (when observed under the filters for those colors) was used as the chromatic shift. The chromatic shifts were determined separately for the x, y and z coordinates (Appendix 4).

The average DNA compaction based on the linear contour length of 340 nm for 1.0 kb was calculated as follows:

$$\frac{\text{genomic length [kb]}}{\text{spatial distance [nm]}} \cdot 340 \text{ [nm/kb]}$$

Kratky-Porod Description of a Semi-flexible Polymer

The Kratky-Porod description of a semi-flexible polymer was used to compare the experimental data to that of the worm-like chain:³⁵

$$\langle R^2 \rangle = 2 \cdot L^2 \cdot \left(\frac{d}{cL} - 1 + e^{-\frac{d}{cL}} \right)$$

where R indicates physical distance between genetic markers (nm), d refers to genomic separation between genetic markers (bp), c indicates DNA mass density (bp/nm), and L refers to the persistence length (nm).

Probability Distribution for a 3D Random Walk

The frequency distribution of the physical distances between the probes was determined in intervals of 100 nm, and the cumulative frequencies were plotted against the physical distances. The cumulative frequency indicates the fraction of the population of probes that lies within a certain physical distance from each other. Cumulative frequencies were also determined for the random walk model for a polymer chain. For this purpose, DNA was assumed to have a mass density of 130 bp/nm.³⁴ Consider two genomic probes separated by 'd' base pairs. If one probe is considered as a reference, the probability that the displacement of the second probe with respect to the first probe is '**R**' is given by:

$$P(R, a) = \left(\frac{3c}{2\pi da} \right)^{\frac{3}{2}} e^{-\frac{3cR^2}{2da}}$$

where 'a' is the Kuhn length of DNA (nm) and c is the DNA mass density (bp/nm).⁴⁹ To obtain the probability that the second probe lies within a physical distance R nm from the first probe, one needs to evaluate the probability that the second probe lies anywhere within a sphere of radius R nm with the first probe at its center. This is given by:

$$\int_0^R \left(\frac{3c}{2\pi da} \right)^{\frac{3}{2}} e^{-\frac{3cR^2}{2da}} 4\pi R^2 dR$$

This is the fraction of the population of probes that are separated by a distance of up to R nm. This gives the cumulative distribution function for the random walk model for polymers. The cumulative frequencies were determined for different persistence lengths and compared with the experimental data.

Computer Simulations

Using a two-step combined Monte-Carlo and Brownian Dynamics method, the Random-Walk/Giant-Loop (RW/GL) model¹² and the Multi-Loop Subcompartment (MLS) model¹¹ were simulated for human interphase chromosome 15.^{3, 15, 50}

Assuming a flexible polymer chain, the chromatin fiber was split into ~3,300 segments of 300 nm (~31 kb). To each segment a harmonic stretching potential and between two segments a harmonic bending potential were assigned. To avoid self-crossing of the polymer chain, a short ranged excluded volume potential was introduced, whose potential barrier could be changed to facilitate chain dis-entanglement to speed up simulations. The simulation of single chromosomes necessitated placement into an embedding potential simulating the surrounding nuclear chromosomes. In the RW/GL model loops of 5.0, 4.0, 3.0, 2.0, 1.0, 0.504 and 0.252 Mb were used and connected by a chromatin spacer whose length was adjusted such that the global territory behavior yielded comparable results as in the MLS model. In the MLS model the loop size was 126 kb with spacer sizes of 63, 126, 189 and 252 kb. The number of loops in the rosettes varied, since the DNA content of the rosettes was assumed to be that of the metaphase ideogram banding pattern⁵¹ divided by three to account for the transition into interphase ideogram bands.⁵² The starting configuration of a chromosome had the approximate form and size of a metaphase-chromosome whose de-condensation resembles the natural process. Typically ~400,000 Monte Carlo steps were needed to generate enough statistically independent configurations at thermodynamic equilibrium. For comparison with experimental spatial distance measurements between genetic markers as function of their genetic separation, 100 to 150 statistically independent Monte Carlo configurations were taken as starting points for relaxation at higher spatial resolution by Brownian Dynamics methods using a decreased segment length of 50 nm (~5.2 kb), corresponding to 20,000 segments for chromosome 15. 2,000 Brownian Dynamics steps were performed until equilibration was reached again. The simulated spatial distances were determined position dependently, i.e. the marker pairs were placed in respect to the topological folding of the simulated chromosome and position independently, i.e. the pairs of markers were placed randomly and therefore regardless of any folding topology on the chromosome (for the underlying assumption see Results). All pairs of positions for one genomic separation were taken, the resulting spatial distance determined and averaged over one and the 100 to 150 statistically independent chromosome configurations.

ABSTRACT

Most genetic disruptions underlying human disease are micro-lesions, whereas gross lesions are rare with gross deletions being most frequently found (6 %). Similar observations have been made in primary immunodeficiency genes, such as *BTK*, but for unknown reasons the *IGHM* and *DCLRE1C* (*Artemis*) gene defects frequently represent gross deletions (58 % and 46 %, respectively). We characterized the gross deletion breakpoints in *IGHM*-, *BTK*- and *Artemis*-deficient patients. The *IGHM* deletion breakpoints did not show involvement of recombination signal sequences or immunoglobulin switch regions. Instead, similar to *BTK* and *Artemis* deletions, most *IGHM* breakpoints were located in or near sequences derived from transposable elements (TE). A role for these elements in mediating gross deletions in other genes disrupted in human disease has been suggested, but has never been specified. We found that *IGHM*, *BTK* and *Artemis* gross deletion breakpoints were frequently located in TEs belonging to types that were specifically overrepresented in the involved gene as compared to the average in the human genome. This concerned both long (LINE1) and short (*Alu*, MIR) interspersed elements, as well as LTR retrotransposons (ERV). Furthermore, a high total TE content (>40 %) was associated with an increased frequency of gross deletions. Both findings were further investigated and confirmed in a total set of 20 genes disrupted in human disease. Thus, for the first time, we provide evidence that a high TE content, irrespective of the type of element, results in the increased incidence of gross deletions as gene disruption underlying human disease.

KEY WORDS

Gross deletion, transposable element, *IGH*, *BTK*, *Artemis*.

INTRODUCTION

The majority of gene disruptions underlying human inherited diseases are micro-lesions, i.e. single basepair substitutions (68 %) and small (<20 nt) deletions or insertions (25 %).¹ Gross lesions are less common, with gross deletions being most frequently found (6 %).¹ For gross deletions to occur, three conditions have to be met: (a) two double-stranded DNA breaks in distinct genomic locations that are (b) physically located in close proximity in order to (c) undergo incorrect repair. Based on limited sequence data of the junctions of gross deletion breakpoints in disease-causing alleles, three mechanisms have been described: 1) Mispairing of homologous sequences and unequal crossing over; 2) Non-homologous deletions; 3) Mispairing between two *Alu* short interspersed elements (SINE) and crossing-over.² Recent analysis of several gross deletion breakpoints indicates a role for single-strand annealing of repeated fragments in gross lesions.³ Although this mechanism could explain incorrect repair of complex DNA structures, it remains unclear how two genomically distinct sites become located in close proximity.

The human genome contains four classes of interspersed repeats that are derived from transposable elements (TE) and comprise about 45 % of the total sequence.⁴ Besides the above-mentioned SINEs, these are long interspersed elements (LINE), LTR retrotransposons and DNA transposons. Non-homologous gross deletion breakpoints are frequently located in or near these TEs,^{5,6} but the role of these repeats in mediating gross deletions is currently unknown.

Although inherited disorders of the immune system are rare, multiple gene defects have been identified during the last 15 years, mainly concerning micro-lesions.⁷ However, gross deletions have also been found, for example involving the *DCLRE1C* (*Artemis*), *BTK* and immunoglobulin C μ heavy chain (*IGHM*) genes.⁸⁻¹³ The gross deletion frequency of *BTK* disruptions is 6 %, whereas about half of the reported disease-causing alleles of *IGHM* and *Artemis* are disrupted by gross deletions.^{1,8,13} A mechanism underlying this striking difference has never been reported.

The immunoglobulin heavy chain (IgH) is part of the antibody molecule and is produced by B cells after V(D)J recombination of the *IGH* locus. The *IGH* locus contains multiple V_H, D_H and J_H gene segments and constant (C_H) regions. The V_H, D_H and J_H gene segments are flanked by recombination signal sequences (RSS) that are recognized by the recombinase machinery,¹⁴ which is specifically expressed during precursor-B-cell differentiation to generate a functional VDJ exon.¹⁵ The VDJ exon is initially spliced to the C μ exons. During an immune response, genomic Ig class switch recombination can take place to replace the C μ exons for one of the other C_H regions. This process is mediated by the Ig switch regions.¹⁶ Similar to V(D)J recombination, Ig class switch recombination involves the genomic deletion of a large intervening DNA sequence.

Gross deletions involving *IGHM* can be up to 300 kb and can include upstream D_H and V_H gene segments and downstream constant gene regions.¹¹⁻¹³ We hypothesized that the complexity of the *IGH* locus contributes to the increased incidence of *IGHM*-disrupting gross deletions. Possible mediators are the RSS and Ig switch regions, which are target sequences for B-cell specific recombination events. Furthermore, germline duplications and deletions of Ig subclasses have been reported.¹⁷⁻²⁰ The C_H regions contain high degrees of sequence

homology and the altered haplotypes are thought to be the result of mispairing between highly homologous regions and subsequent unequal crossing-over during meiosis.¹⁷⁻²²

In this study, we aimed to identify mechanisms that underlie the high frequency of gross deletions disrupting *IGHM* and *Artemis* as compared to *BTK*. Breakpoint analysis suggested involvement of TEs rather than recombination motifs. We hypothesized that the TE content of a gene is related to the gross deletions frequency, and this hypothesis was tested on 20 genes disrupted in human disease.

MATERIALS AND METHODS

Patient DNA isolation and PCR amplification

Genomic DNA was isolated from post-Ficoll PB granulocytes with the GenElute Mammalian Genomic DNA Miniprep Kit (Sigma-Aldrich, St. Louis, MO). The sizes of the gross deletions in *IGHM*, *BTK* and *Artemis* deficient patients were determined with scanning PCRs for gene segments, exons and subsequently for intronic regions. Seven unrelated *IGHM*-deficient patients with a homozygous gross deletion were studied. Of these patients, three were previously published as having a gross deletion (F2, F7 and SIOC),¹¹⁻¹³ and the other four were newly identified (BN, ID392, ID393 and ID394). Furthermore, three unrelated patients with a hemizygous deletion of *BTK* (ID113, ID434, ID440), and five unrelated patients with a homozygous deletion of *Artemis* (ID020, ID024, ID124, ID176, ID389) were studied. PCR reactions were essentially performed as described before with primers were designed to specifically amplify 200-600 bp of DNA (primer sequences shown in Appendices 7-9).²³

Long-range (LR)-PCR, ligation-mediated (LM)-PCR and DNA sequencing for analysis of the breakpoint junctions

LR-PCR was performed as described before using the appropriate forward and reverse primers that were used to map the gross deletion boundaries.²⁴

LM-PCR was essentially performed as described before with newly designed primers. Aliquots of 1 mg high molecular weight DNA were digested with blunt-end restriction enzymes (*DraI*, *HincII*, *PvuII* and *StuI*) and 50 mM of an adaptor (Clontech, Palo Alto, CA, USA) was ligated to both ends of the restriction fragments.²⁵ The ligation products were subjected to two rounds of PCR with nested adaptor-specific primers AP1 and AP2 (Clontech) and sets of primers designed upstream of the 5' end of the breakpoint. Atypical bands that appeared from patient's DNA, but not from control DNA were excised from the gel, purified using the QIAquick Gel Extraction Kit (Qiagen, Valencia, CA) and sequenced on an ABI Prism 7700 sequence detection system (Applied Biosystems, Foster City, CA).

Human disease-causing mutation data

Mutation data of genes disrupted in human disease were extracted from the February 2007 release of the human gene mutation database (HGMD).¹ To calculate the gross deletion frequency, we included the newly described gross deletion alleles from *IGHM*- and *Artemis*-deficient patients from this study, and newly identified *BLNK* mutations (unpublished results).

Sequence analysis of genes and breakpoint regions

Sequences of the *IGH* locus (NCBI: NG_001019.5), and the *BTK*, *Artemis* (*DCLRE1C*), *BLNK*, *APC*, *ATM*, *BRCA1*, *BRCA2*, *CFTR*, *DMD*, *Factor VIII*, *FANCA*, *HPRT1*, *LDLR*, *MECP2*, *MLH1*, *MSH2*, *NF1*, *RBI* and *VWF* genes including 10 kb upstream and downstream sequences, extracted from Ensembl v42 – Dec2006,²⁶ were annotated with TE-derived interspersed repeats by the CENSOR software tool of the Repbase database.²⁷ To obtain representative TE content frequencies, only genes spanning more than 50 kb were included.

The identified breakpoint regions were aligned with the gene sequences extracted from public databases. The Genewindow website was used to identify whether mismatches with standard sequences were previously described polymorphisms.²⁸ Complexity analysis of ± 25 bp flanking the breakpoint regions was performed to examine the potential contribution of local sequence structure to the mechanism of gross deletion in the *IGH* locus and the *BTK* and *Artemis* genes.^{3, 29} In addition, the same region was scanned for the presence of 24 sequence motifs known to be associated with site-specific recombination, mutation, cleavage and gene rearrangement.² The sequences $\pm 1,000$ bp flanking the breakpoint regions were annotated with TEs by the CENSOR software tool of the Repbase database.²⁷

Statistical analysis

Differences in gross deletion frequencies were analyzed by using the non-parametric Mann-Whitney test (one-tailed; $P > 0.05$) in the GraphPad Prism program (GraphPad Software, San Diego, CA, USA).

RESULTS

Identification of five unique gross deletion breakpoint junctions in seven homozygous *IGHM*-deficient patients

DNA material was collected from four previously described and three newly identified unrelated patients with a full block in precursor-B-cell differentiation in bone marrow resulting from a homozygous deletion of *IGHM*. For each of these seven patients, the extent of the deletions was studied with newly designed and tested PCR amplicons recognizing unique V_H and D_H gene segments and *IGH* constant gene regions (Figure 1A). Subsequently, additional PCR amplicons were designed to refine the position of the breakpoints within 2-3 kb to enable cloning of the breakpoint fusion with either LM-PCR or LR-PCR. This approach resulted in the characterization of five unique breakpoint junctions within the *IGH* loci of the seven *IGHM*-deficient patients (Figure 1A).

Patient BN was found to carry a homozygous *IGHM* deletion of 732 kb including V_H3-37 until *IGHGP* (Figure 1A). The junction contained nine bp of unique sequence that could not be assigned to the 5' or 3' breakpoint region sequences (Figure 1B). The two mismatches with the 5' breakpoint region corresponded to previously described single nucleotide polymorphisms (SNP).

In addition to the *IGHM* deletion, the homozygous *IGH* locus of patient BN had a 33 kb deletion involving the V_H3-39 , V_H7-40 and V_H3-41 gene segments. About 1.3 kb sequence in-between the two gross deletions including the V_H3-38 gene segment was still present

on the locus. The junction of the 33 kb deletion contains 2 bp microhomology and shows high degrees of sequence homology between the regions downstream of the breakpoints (Figure 1B). None of the other six *IGHM* patients carried this deletion. To test whether the 33 kb V_H deletion is a polymorphism that is not related to the *IGHM* disruption, 66 controls were screened for this deletion. We found that 15 of 66 controls carried this deletion, but not the *IGHM* deletion; 7 were heterozygous and 8 homozygous. The breakpoint flanking sequences (200 bp) of the 23 control alleles were identical to patient BN including the six nucleotides that differed from the standard *IGH* sequence (Figure 1B). From this, we concluded that the 33 kb deletion of V_{H3-39} , V_{H7-40} and V_{H3-41} is apparently a common polymorphism as it was present in 17 % of the *IGH* alleles in controls.

Identical breakpoint junctions were found in two unrelated patients: ID393 and ID394. Both patients lack 578 kb of genomic DNA starting from the V_{H3-19} gene segment and ending 3' of the *IGHG4* constant region. The two breakpoints were fused with a three-nucleotide microhomology region (Figure 1B). PCR amplicons flanking the breakpoint, V_{H3-20} , *IGHE* and *IGHA2* were screened for 21 previously identified SNPs. The amplicons showed identical sequences for both patients: 11 sites differed from the standard sequence, 5 of which are known SNPs. Thus, these patients carry the same allele, which they inherited from a common ancestor.

The two unrelated patients ID392 and F7 also carried deleted alleles with identical breakpoint junctions. The deletions span 126 kb of genomic DNA starting at the KIAA0125 element in-between the V_{H6-1} and D_{H1-1} gene segments and ending 3' of *IGHD* (Figure 1B). One nucleotide microhomology was found at the breakpoint fusion (Figure 1B). Interestingly, 5' of the breakpoint junction of both patients, a small deletion of 19 bp with 6 bp microhomology in the fusion was found. This small deletion was not seen in 82 controls, indicating that this is not a common polymorphism. Taking into account the close proximity to the gross deletion breakpoint, we suggest that both the small and the gross deletion occurred in the same event. SNP analysis of the breakpoint fusion region, V_{H3-20} , $V_{HIV-20.1}$ and *IGHE* PCR amplicons showed no polymorphic differences between the alleles of patients ID392 and F7, indicating that both patients inherited the allele from a common ancestor.

The gross deletion in patient F2 spanned 71 kb from D_{H1-1} to *IGHM*. Interestingly, the junction contained a 51 nt insertion, which aligned almost perfectly with the intronic region in-between D_{H4-23} and D_{H5-24} , 37 kb downstream of the 5' breakpoint (Figure 1A). Consequently, two deletions were found; the two junctions contained 1 and 3 nucleotides of microhomology, respectively (Figure 1B). The 5' deletion that does not involve *IGHM* was not found in 66 controls. Therefore, it does not appear to be a common polymorphism.

Patient SIOC had a gross deletion of 146 kb extending from D_{H6-13} to *IGHG3* (Figure 1A). The junction contains 4 nucleotides of microhomology (Figure 1B).

We identified 5 unique breakpoint junctions in 7 unrelated homozygous *IGHM*-deficient patients. Two previously identified *IGHM*-deficient patients, who were heterozygous for a gross deletion, did not carry one of the identified breakpoint junctions and are likely to carry unique deletions.¹³ All 5 identified breakpoint junctions demonstrated the characteristics of non-homologous recombination with four out of five showing microhomology and one with an insertion of six nucleotides. Furthermore, both the 5' and the 3' breakpoints were scattered throughout the *IGH* locus and did not co-localize with RSS or Ig switch regions, thus

Figure 1. Gross deletion breakpoints of seven unrelated homozygous *IGHM*-deficient patients.

A. *IGHM* gross deletions ranging in size from 71 to 732 kb were identified using a PCR approach. An additional 33 kb deletion 1.6 kb upstream of the *IGHM* deletion disrupts three V_H gene segments in patient BN. **B.** Sequences of the five unique *IGHM*-deleting breakpoint junctions and one novel V_H deletion polymorphism. The *IGHM*-deletion breakpoint junction of patient BN shows a 9-nucleotide insertion (caps). The two mismatches with the 5' breakpoint region are previously described SNPs. The 33 kb V_H-deletion polymorphism in patient BN shows a dinucleotide microhomology (boxed). The *IGHM*-deletion in patients ID393 and ID394 shows a trinucleotide microhomology. The *IGHM*-deletion in patients ID392 and F7 shows one nucleotide microhomology. The small deletion and the mismatch with the 5' breakpoint region are not previously described polymorphisms. The *IGHM* deletion in patient F2 shows a 55-nucleotide insertion that correspond to the intronic region in-between DH4-23 and DH5-24. The 5' junctions showed one nucleotide microhomology, whereas the 3' junction showed three nucleotides of microhomology. The mismatch within the 55 nt insertion is not a previously described SNP. Complexity analysis of ± 25 bp flanking the breakpoints showed that the deletions in patients ID393, ID394 and SIOC are potentially mediated by a hairpin loop (inverted repeats). The deletion in patients ID392 and F7 could have been mediated by a knot structure. Furthermore, the deletion in patient F2 is potentially mediated by combination of a knot structure for the 5' joint and a Möbius loop for the 3' joint.

indicating that no preferential well-established recombination sites were targeted. No common sequence motifs were found in the breakpoint regions, but complexity analysis of the breakpoint regions showed the likely involvement of repeated fragments (Figure 1B).

***IGH* breakpoints are associate with TEs**

The five identified *IGH* breakpoints were located in intronic sequences without any apparent homology between the 5' and 3' breakpoint flanking regions. In order to study the involvement of TEs, 2 kb DNA sequences flanking the breakpoint regions were screened against a reference collection of repeats. As shown in Figure 2, we found that 2 of the 10 *IGHM*-deleting breakpoints were located in or near a LINE 1 and 6 were located in or near endogenous retroviral (ERV) sequences, which belong to the class of LTR retrotransposons. The remaining 2 breakpoints were located in unique sequences. Consequently, in almost all gross deletions involving *IGHM*, the breakpoints of fusion partners are located in or near repetitive elements of the same class. Since TEs are present throughout the genome and they have been implicated in genomic rearrangements,^{5, 6} the localization of gross deletions in or near TEs could be a general phenomenon.

Figure 2. *IGHM*-deletion breakpoints are located in or near repetitive elements.

± 1,000 bp flanking the 10 unique breakpoints involved in *IGHM* deletions were analyzed for the presence of transposon-derived repetitive elements. No *V_H*, *D_H*, *J_H* gene segments or constant gene exons were present in these regions.

Similar to *IGHM*, gross deletion breakpoints in *BTK* and *Artemis* frequently occur in TEs

In addition to *IGH*, gross deletions disrupting *BTK* or *Artemis* have been found in primary immunodeficiencies (PID). Although only 5 of 37 identified breakpoints have been analyzed at sequence level, similar to *IGHM* gross deletions, the majority of the *BTK* breakpoints was located in repetitive elements.^{30, 31}

In addition to the published sequences, we identified three additional gross deletions in *BTK*-deficient patients. The eight deletions are spread throughout the gene and range in size from 2.6 to 38.2 kb deleting one or more exons (Figure 3A). The results of the breakpoint sequence analyses of our three patients were in line with previous observations (Figure 3B and C). In 6 of the 8 patients, 5' and 3' breakpoints were located in *Alu* repeats and showed high degrees of sequence homology (Figure 3B and refs. 30, 31). Interestingly, 2 *Alu* motifs were found to be involved in two independent recombination events. In both cases, the breaks occurred at distinct sites within the *Alu* motifs, although the 3' breakpoint of patient P4 is located closely to the 3' breakpoint of patient ID434 (Figure 3B).

The gross deletion breakpoints in patients 0703 and ID440 were not located in *Alu* elements and did not show sequence homology within 50 bp. Patient 0703 had 1 nucleotide of microhomology at the junction,³⁰ whereas 2 nucleotides were inserted in the junction of patient ID440. The 5' breakpoint of patient 0703 was located near a MIRb (SINE2) sequence, whereas the 3' breakpoint was located in a LINE1 element and near an *Alu* element (Figure 3C). In patient ID440, the breakpoints were also located closely to SINE elements; the 5' breakpoint downstream of a MIRb and the 3' breakpoint downstream of an *Alu* repeat.

In general, the gross deletions in *BTK* were much smaller than those characterized in the *IGH* locus. This was especially noted for the *Alu* – *Alu* recombination events. Detailed TE annotation of breakpoint flanking regions (Figure 3C) showed that all eight gross deletion breakpoints in *BTK* were located in or near TEs.

In contrast to *BTK*, *Artemis* gross deletion breakpoints have not been sequenced to date. We identified two unique breakpoint regions in five homozygous *Artemis*-deficient patients (Figure 4A). Patient ID124 carried a deletion of ~82 kb including exons 1, 2 and 3 of the *Artemis* gene. A homozygous deletion of ~82 kb including exons 1, 2 and 3 of *Artemis* was found in patients ID020, ID024 and ID176. Patient ID389 had an 11.1 kb genomic deletion including *Artemis* exons 10, 11 and 12. The 5' and 3' breakpoints were located in *Alu* sequences and the joint showed high degrees of sequence homology (Figure 4B and C).

High total TE content associated with increased incidence of gene-disrupting gross deletions

Although the incidence of gross deletions in *IGHM*, *BTK* and *Artemis* differs greatly (58 %, 6 % and 46 % of disease-causing mutations, respectively), the majority of gross deletions in all three genes show involvement of TEs. To address this difference, we determined the total TE content in these genes and compared this TE content to that of the total human genome (Figure 5A). We found that the TE content of *IGH* (41 %) and *Artemis* (45 %) was higher than the average of the human genome (37 %). In contrast, only 29 % of the *BTK* gene consists of TE-derived repeats. Similar analysis was performed for *BLNK*, which is also a PID gene of >50 kb in size. Only three disease-causing mutations in *BLNK* have been

identified, which were all micro-lesions. Similar to *BTK*, a reduced fraction of the *BLNK* gene consisted of TEs (Figure 5A; 30 %). These observations indicate that a high total TE content of a gene is associated with an increased gross deletion frequency found in gene disruptions underlying human disease.

Of the four types of TEs that are most frequently found in the human genome (LINE1, ERV, *Alu*, MIR), the ERV and LINE 1 content is over-represented in *IGH* compared to the average in the human genome (Figure 5B). In contrast, *BTK* and *Artemis* have very few of these TE elements, whereas twice as much of their genomic sequence is derived from *Alu* motifs as compared to the average in the human genome. None of the four dominant types of TEs was overrepresented in *BLNK*. Whereas the total TE content is correlated to the gross deletion frequency, gross deletions involve mainly TEs belonging to a class that is overrepresented in a gene, irrespective of the total TE content.

TEs and gross deletions in human disease genes

We demonstrated an association between the TE content and the gross deletion frequency of four genes implicated in primary immunodeficiencies. This is a small set of genes and with the exception of *BTK*, only a limited number of disease-causing mutations have been identified in these genes: 12 *IGHM* mutations; 13 *Artemis* mutations; 3 *BLNK* mutations (Table 1). Therefore, we decided to test our model in a larger set of extensively studied human disease genes. A literature search yielded a set of 16 additional genes. The gross deletion frequency of these genes in human disease was extracted from the HGMD,¹ and the TE content was determined with CENSOR.²⁷ Similar to what was observed for the initial four genes, the genes with a higher TE content tended to show an increased frequency of gross deletions (Table 1). A strong increase in the gross deletion frequency was noted in genes that showed >40 % TE content (Table 1). The median gross deletion frequency was 6 % for genes with <=40 % repetitive elements, compared with 14 % for genes with >40 % repetitive elements

Figure 3. Gross deletions in *BTK* are mainly associated with *Alu* – *Alu* mispairing and crossing over.

A. (facing page) Mapping of the *BTK* gross deletions in three unrelated patients using a PCR approach. The gross deletions in patients 0703, 0850, 2430, 2433³⁰ and P4³¹ have been described before. **B.** (facing page) Sequences of the three newly identified breakpoint junctions compared to control sequences. The breakpoint junction of patient ID440 shows a TT insertion, which could be palindromic nucleotides. Microhomology regions at the junctions of patients ID113 and ID434 are boxed. Complexity analysis of ± 25 bp flanking the breakpoints did not result in a likely mediator for patient ID440, whereas the breakpoint in patients ID113, 0850, ID434, P4, 2430 and 2433 appear to be mediated by homologous recombination and in patient 0703 by a knot structure (inversion of inverted repeats). The 3' breakpoint of patient P4 was located close to the 3' breakpoint of patient ID434 and the 6 nucleotides of microhomology are indicated by bold font in the 3' breakpoint region of ID434. **C.** $\pm 1,000$ bp flanking the 16 unique *BTK* gross deletion breakpoints were analyzed for transposon-derived repetitive elements. In addition, *BTK* exons are indicated. The 3' breakpoints of patients ID434 and P4 were located in the same *Alu* element, and the 3' breakpoint of patient 0850 and the 5' breakpoint of patient P4 were located in the same *Alu* element.

IV

Figure 4. Gross deletions in the *Artemis* gene suggest *Alu* – *Alu* mispairing and crossing over.

A. Mapping of the homozygous *Artemis* gross deletions in five unrelated patients using a PCR approach. **B.** The deletion in patient ID389 is potentially mediated by homologous recombination. **C.** The deletion breakpoints of patient ID389 are located in *Alu* elements.

(Figure 6A). This difference was found to be highly significant between both groups of genes ($p = 0.006$).

Gross deletions are currently defined as > 20 bp, which is a crude cut-off value. TEs in the human genome range in size from about 300 bp to several kb. Consequently, this would imply that only gross deletions spanning more than a few hundred bp can show involvement of two independent TEs in a gross deletion. To test whether this holds true, additional analyses were performed with cut-off values for gross deletions of 200 and 400 bp. These analyses mainly showed a remarkable reduction in gross deletion frequency of *MECP2* from 34 % to 13 % with a cut-off of 400 bp. No difference was found for the median values and the significance for the 200 bp cut-off, whereas the medians were 5 % and 13 % for genes with ≤ 40 % and > 40 % sequence derived from TEs, respectively, with $p = 0.005$ (Figure 6B). In conclusion, genes with a TE content of > 40 % have a significantly increased gross deletion frequency in mutations underlying human disease. The significance increased slightly when the cut-off for gross deletions is increased to 400 bp.

In addition to the total TE content, the content of the four most abundant TE subclasses (ERV, LINE1, *Alu* and MIR) was determined for the 20 genes to study whether the overrepresented elements were specifically involved in gross deletions (Table 1).

Although the breakpoint fusion sequence of only a small fraction of the reported gross deletions has been determined, mainly the overrepresented TE subclasses appeared to be involved in gross deletion breakpoints (Table 1).

Figure 5. Highly variable TE content in four genes.

A. The *IGH* and *Artemis* loci contain a high TE content compared to the average of the human genome, whereas the *BTK* and *BLNK* genes have decreased TE content. **B.** The LINE, ERV, *Alu* and MIR elements are the most common TEs found in the human genome. *IGH* contains an increased ERV and LINE content, whereas *BTK* and *Artemis* mainly contain *Alu* elements. *BLNK* does not display increased presence of any of the four types of elements as compared to the average of the human genome.

DISCUSSION

We characterized the gross deletion breakpoints in *IGHM*-, *BTK*-, and *Artemis*-deficient patients to explain the high frequency of gross deletions in *IGHM* and *Artemis* compared to *BTK*. *IGHM* gross deletion breakpoints were not located in or near RSS or Ig switch regions, but similar to gross deletions involving *BTK* or *Artemis*, they were associated with TE-derived repeats. A model based on differential TE involvement and gross deletion frequencies of these genes was tested on a total set of 20 genes disrupted in human disease. We found that gross deletion breakpoints in each gene were frequently located in TE types that were specifically overrepresented in that gene as compared to the average in the human genome. Furthermore, we found that genes with a high TE content (>40 %) showed an increased frequency of gross deletions when disrupted in human disease. We conclude that, similar to suggestions based on limited sequence data from other genes disrupted in human disease, repetitive elements are likely mediators of gross deletions in *IGHM*, *BTK* and *Artemis*.

In this study, five unique breakpoint regions were characterized in seven unrelated *IGHM*-deficient patients. The breakpoints were scattered throughout the locus in introns within the V_H , D_H and CH regions, thus indicating that there was no preferential targeting of a specific region. Interestingly, no co-localization with RSS or Ig switch regions was found.

Table 1. Correlation gross deletions incidence and TE content.

^f Data obtained on the total human genome sequence

Figure 6. Genes disrupted in human inherited diseases with a transposon-derived repetitive element content of > 40 % are significantly more frequently disrupted by gross deletions than genes with ≤ 40 % TE content. The frequency of gross deletions was determined from 20 genes disrupted in human inherited disease. A surprising increase in gross deletion frequency was found in genes with > 40 % TE content. **A.** The gross deletion frequency of 20 genes is shown for genes with ≤ 40 % and > 40 % TE content. Every dot represents an individual gene. The gross deletion frequency was significantly increased in genes with > 40 % TE content as determined with a non-parametric test. **B.** The significance increases slightly when the cut-off set for gross deletions is increased from > 20 bp to > 400 bp.

Whereas such sequences are potent recombination sequences in specific stages during B-cell development, they do not appear to be recombination-prone in germline cells. It is therefore highly unlikely that the B-cell specific recombination characteristics of the *IGH* locus underlie the high frequency of gross deletions involving *IGHM*.

The five *IGHM* deletions did not show high sequence homology between the 5' and the 3' breakpoint regions. Therefore, it is unlikely that the gross deletions were the result of mispairing of homologous sequences and unequal crossing-over as has been observed in recurrent Ig subclass deletions.²² The five breakpoint junctions did show the characteristics of NHEJ with microhomology in four joints and an insertion of six nucleotides in the fifth. No common sequence motifs were found in the breakpoint regions, whereas complexity analysis revealed that short repetitive sequences are likely mediators of the unequal repair.

In addition to the disease-causing *IGHM* deletion in patient BN, a 33 kb deletion of three *V_H* gene segments was found. Because 17 % of the alleles in healthy controls carried the exact same 33 kb deletion, but not the *IGHM* deletion, we conclude that this is a common polymorphism. This polymorphism likely arose by homologous unequal recombination prior to and independently from the *IGHM* deletion. Since the polymorphism is located quite distant from the 5' *IGHM* deletion breakpoint (1.6 kb), it is unlikely that this polymorphism made the *IGH* allele more susceptible to the deleterious deletion.

The gross deletion junction of patients ID392 and F7 and of patient F2 also revealed that two deletions had disrupted the *IGH* locus (Figure 1). In both cases, the 3' deletion disrupts *IGHM* and therefore underlies the disease. The 5' micro-deletion in patients ID392 and F7 and the 5' gross deletion in patient F2 were located in close proximity to the 5' gross deletions (54 and 51 bp, respectively) and not found in controls. Although the 5' deletion restricts

the D_H repertoire by removing 23 of the 27 D_H gene segments, the remaining four D_H gene segments should be sufficient for B-cell development and immune function.³² Because deleterious *IGHM* mutations are very rare, it is unlikely that the double deletions are the result of two independent hits. Furthermore, similar observations were made in a *TCF2* gross deletion in a patient with Maturity-onset diabetes of the young type 5.³³ A 55-bp insertion corresponding to part of the deleted DNA sequence was inserted in the inverse orientation. These observations led the authors to conclude that the deletion was the result of a single event. Considering the rarity of gross deletions and the similarities with the *TCF2* deletion, we propose that the deletions in patients ID392 and F7 and in patient F2 arose in a single event during which two regions were looped out and incorrectly repaired, thus resulting in the complicated junction we observed (Figure 1).

The majority of *IGHM*-deleting gross deletion breakpoints were located in or near TE-derived repeats. Interestingly, the involved elements (LINEs and LTR retrotransposons) were overrepresented in the *IGH* locus as compared to the average in the human genome. On the other hand, the gross deletions identified in *BTK*- and *Artemis*-deficient patients mainly involved SINES. In contrast to *IGH*, these SINES are specifically overrepresented in *BTK* and *Artemis*. Furthermore, the high frequency of gross deletions in *IGH* and *Artemis* as compared to *BTK* and *BLNK* was associated with a high total TE content. These observations suggest a role for TEs in mediating gross deletions. Involvement of TEs has been suggested before.^{5, 6} However, by analysis of 20 genes disrupted in human disease, we are the first to show that the total TE content is associated with a significantly increased frequency of gross deletions as cause of gene disruption.

The role of TEs in mediating gross deletions is difficult to examine. In general, the breakpoints analyzed in this study involved at least two double-stranded DNA breaks in distant genomic locations (2.6–732 kb) that were placed in physical proximity and incorrectly repaired. Complexity analysis showed that small repeat fragments are likely mediators of the incorrect repair. This mechanism is quite similar to what is seen in micro-lesions, which are thought to result from slipped mispairing of single-stranded DNA in the replication fork. Since the stretches of single-stranded DNA in the replication fork do not extend beyond 1,000-2,000 bp, additional factors are required to mediate co-localization of two distant genomic regions and double-stranded DNA break induction.

Studies in *Drosophila* have demonstrated the accumulation of transposon-derived repetitive elements in heterochromatin and this appears to be widespread among higher eukaryotes (reviewed by Dimitri *et al.*³⁴). Since genes packed in heterochromatin are commonly repressed, the accumulation of TEs in heterochromatin could result from the preferential insertion of these elements in DNA sequences packed in heterochromatin, or from a mechanism that recruits DNA with high TE content to heterochromatin. Although the latter mechanism was observed recently in *Arabidopsis*,³⁵ this does not exclude the other mechanism. Heterochromatic regions are compact clusters of genomic DNA. It seems therefore likely that genomic regions with high TE content are tightly packed in heterochromatin, and this is the mechanism by which TEs mediate co-localization of distant genomic regions.

Micro-insertions and micro-deletions are assumed to result from slipped mispairing, but this mechanism has been proposed to underlie some of the identified deletions that were >20 bp.³⁶ This is not remarkable as it is suggested to result from mispairing of ssDNA in

the replication fork and the length of ssDNA is 1,000-2,000 bp. However, TEs are a few hundred or a few thousand bp in size. Therefore, the involvement of TEs in the generation of deletions smaller than a few hundred bp is unlikely. We suggest defining gross deletions to be larger than 400 or even 1,000 bp because this better reflects the mechanism underlying these lesions. Ultimately, additional sequence data and analysis of deletion breakpoints should allow for a more accurate discrimination of micro- and gross deletions based on the underlying mechanism.

In this study, we identified and characterized *IGHM*, *BTK* and *Artemis* deletions in patients with primary immunodeficiency. Analysis of these deletion junctions formed the basis of our model, which was confirmed by analysis of 20 genes disrupted in human disease. This model states that: (a) Gross deletions are mediated by TE subclasses that are specifically overrepresented in the involved gene as compared to the average in the human genome; and (b) a high total TE content results in an increased frequency of gene disruption by gross deletions. Whereas more sequence data are needed to draw firm conclusions on the underlying mechanisms, this study shows for the first time the impact of TEs on the gross deletion frequency as gene disruption in human disease.

ABSTRACT

Background The CD19 protein forms a complex with CD21, CD81, and CD225 in the membrane of mature B cells. Together with the B-cell antigen receptor, this complex signals the B cell to decrease its threshold for activation by the antigen.

Methods We evaluated four patients from two unrelated families who had increased susceptibility to infection, hypogammaglobulinemia, and normal numbers of mature B cells in blood. We found a mutation in the CD19 gene in all four patients. The CD19 gene in the patients and their first-degree relatives was sequenced, and flowcytometric immunophenotyping of B cells, immunohistochemical staining of lymphoid tissues, and DNA and messenger RNA analysis were performed. B-cell responses on the triggering of the B-cell receptor were investigated by *in vitro* stimulation; the antibody response after vaccination with rabies vaccine was also studied.

Results All four patients had homozygous mutations in the CD19 gene. Levels of CD19 were undetectable in one patient and substantially decreased in the other three. Levels of CD21 were decreased, whereas levels of CD81 and CD225 were normal, in all four patients. The composition of the precursor B-cell compartment in bone marrow and the total numbers of B cells in blood were normal. However, the numbers of CD27⁺ memory B cells and CD5⁺ B cells were decreased. Secondary follicles in lymphoid tissues were small to normal in size and had a normal cellular composition. The few B cells that showed molecular signs of switching from one immunoglobulin class to another contained V_H-C α and V_H-C γ transcripts with somatic mutations. The response of the patients' B cells to *in vitro* stimulation through the B-cell receptor was impaired, and in all four patients, the antibody response to rabies vaccination was poor.

Conclusions Mutation of the CD19 gene causes a type of hypogammaglobulinemia in which the response of mature B cells to antigenic stimulation is defective.

The online version of this article contains supplemental material.

INTRODUCTION

Primary antibody deficiencies, which are associated mainly with susceptibility to bacterial infections, can be caused by mutations in genes involved in B-cell differentiation.¹ Such genetic defects block the differentiation of immature B cells in bone marrow, thereby causing both a deficiency of mature B cells in the peripheral circulation and agammaglobulinemia.²⁻⁸

In disorders involving defects in the maturation process of antigen-responsive B cells, by contrast, there are mature B cells in blood and a deficiency of some, but not all, immunoglobulin classes (dysgammaglobulinemia) or hypogammaglobulinemia. These disorders fall into two categories. The hyper-IgM syndromes are those in which a genetic defect impairs immunoglobulin-class switching (e.g., IgM to IgG) or impairs somatic mutation of immunoglobulin genes (a molecular sign of a response to an antigen), or both.⁹⁻¹²

The second category is common variable immunodeficiency, a syndrome involving hypogammaglobulinemia, recurrent bacterial infections, and a lack of antibody production in response to vaccination. Genetic defects have been found in some patients with common variable immunodeficiency,^{13,14} but no genetic abnormality is evident in more than 80 percent of such patients.

During B-cell differentiation in the bone marrow, the surface molecule CD19 appears early and remains on the B cell until it differentiates into a plasma cell. Four proteins on the surface of mature B cells – CD19, CD21, CD81, and CD225 – form the CD19-complex, which signals in conjunction with the B-cell antigen receptor, thereby decreasing the threshold for receptor-dependent signaling.¹⁵

We describe four patients, from two unrelated families, who had hypogammaglobulinemia and defective CD19. These patients had normal levels of B cells in blood but had undetectable or very low levels of surface CD19, owing to a homozygous mutation in the *CD19* gene. The antibody deficiency in these patients resulted from a subnormal response to antigen by mature B cells.

CASE REPORTS

Patient 1, a girl of Turkish descent and the second child of consanguineous parents (second cousins), was referred to the Selçuk University Hospital in Konya, Turkey, at ten years of age with a seven-month history of intermittent hematuria. She also had a history of recurrent bronchiolitis and bronchopneumonia starting at one year of age and meningitis starting at eight years of age. On physical examination, her heart rate was 118 beats per minute and auscultation of the lung revealed rhonchi and wheezing. The differential blood count was normal, but urinalysis showed microscopic hematuria without proteinuria. The complement levels were normal, tests for antinuclear antibodies were negative, the erythrocyte sedimentation rate was 41 mm per hour, and the level of C-reactive protein was 93 mg per deciliter. The dermal response to purified protein derivative after two vaccinations with bacille Calmette-Guérin was 12 mm. Renal ultrasonography showed no abnormalities; a renal biopsy revealed proliferation of mesangial cells, interstitial edema, and an apparently normal basement membrane of the glomerulus. She was given a diagnosis

Table 1. Baseline characteristics and laboratory findings in four patients with CD19 deficiency.

Characteristic	Patient 1	Patient 2	Patient 3	Patient 4
Sex	female	male	female	female
Age at onset - yr	1	7	6	5
Age at diagnosis - yr	10	35	33	49
Lymphocytes - cells/mm ³				
Total lymphocytes	4480	2182	2508	2059
CD3 ⁺ T cells	3270	1520	1855	1384
CD4 ⁺ T cells	1792	713	1070	620
CD8 ⁺ T cells	1478	720	692	696
CD20 ⁺ B cells	806	286	521	268
CD16 ⁺ CD56 ⁺ Natural Killer cells	313	277	348	288
Serum immunoglobulin level - mg/dl (95 % CI for age- matched controls)*				
IgG level	325 (842-1943)	204 (804-2212)	198 (814-2047)	256 (814-2047)
IgA level	292 (62-390)	18 (99-489)	7 (99-489)	19 (81-538)
IgM level	25 (54-392)	47 (58-324)	30 (68-379)	63 (42-600)
Blood group	A, Rh ⁺	O, Rh ⁺	O, Rh ⁺	O, Rh ⁺
Isohemagglutinin levels	Not detectable	Low	Low	Low

* Serum Ig levels at diagnosis are shown. Subnormal values are given in bold type; CI denotes confidence interval. Age-matched controls have been described previously.²⁷

of postinfectious glomerulonephritis and was also found to have hypogammaglobulinemia (Table 1).

Patients 2, 3, and 4 were siblings, children of unrelated parents of Colombian descent, and were examined at the Primary Immunodeficiencies Clinic of the University of Antioquia in Medellín, Colombia, at 35, 33, and 49 years of age, respectively. All three had had otitis media, sinusitis, and pharyngitis during childhood. In addition, Patient 2 (the index patient) had had four bouts of pneumonia between the ages of 18 and 35 years; more recently, he had received diagnoses of bacterial conjunctivitis and chronic gastritis (*Helicobacter pylori* infection). He was given a diagnosis of hypogammaglobulinemia due to common variable immunodeficiency (Table 1). His two sisters also had hypogammaglobulinemia (Table 1) and histories of recurrent upper respiratory tract infections. Patient 3 first had pneumonia at 20 years of age, herpes zoster at 30 years of age, and more recently, recurrent bacterial conjunctivitis with dacryocystitis and diarrhea. Patient 4 had had pneumonia at eight years of age, recurrent skin abscesses and more bouts of pneumonia during childhood, and chronic diarrhea, bronchitis, and recurrent bacterial conjunctivitis during adulthood. These three patients had had surgery for chronic sinusitis.

Intravenous immune globulin therapy was initiated in all four patients soon after the diagnosis of hypogammaglobulinemia. All patients are now clinically well, with no signs of

lymphoproliferation, cancer, or autoimmunity. The other siblings of both families have normal serum immunoglobulin levels and no symptoms of immunodeficiency. However, one sibling of Patients 2, 3, and 4 was given a diagnosis of systemic lupus erythematosus at 13 years of age, according to the criteria of the American Rheumatism Association.¹⁶

METHODS

Diagnostic workups of blood, biopsy of bone marrow, cervical lymph node, and tonsil, and rabies vaccination were carried out in patients and family members after they provided oral informed consent and according to the guidelines of the local medical ethics committees in Turkey, Colombia, and the Netherlands. Controls provided written consent.

Amplification and sequence analysis of the *CD19* gene

The *CD19* gene on chromosome 16 (16p11.2) spans 7.5 kb of genomic DNA and codes for a protein of 556 amino acids, including the signal peptide.¹⁷ DNA was isolated from granulocytes that had been isolated with the use of Ficoll gradient centrifugation. All 15 exons were amplified by the polymerase chain reaction (PCR; the primer sequences are listed in Appendix 10), and were sequenced on an ABI Prism 377 fluorescent sequencer (Applied Biosystems).

Total complementary DNA (cDNA) was prepared from messenger RNA (mRNA) that had been isolated from the patients' mononuclear cells, as described previously.¹⁸ Fragments of *CD19* cDNA were amplified and sequenced to verify the mutations found in the genomic DNA.

***CD19* transcripts**

Levels of the *CD19* transcript in blood B cells were quantified from reverse-transcribed mRNA from patients' blood mononuclear cells with the use of TaqMan real-time quantitative PCR with newly designed primers and a FAM–TAMRA-labeled fluorogenic probe (sequences are given in Appendix 11). The transcript levels were normalized against those of a control *ABL* gene and corrected for the numbers of B cells as determined by means of flowcytometric analysis.¹⁹

Analysis of somatic hypermutation

Hypermutation of immunoglobulin genes was studied in the $V_{H3-C\alpha}$, $V_{H4-C\alpha}$, $V_{H3-C\gamma}$, and $V_{H4-C\gamma}$ fragments, which were amplified from the cDNA and cloned into a pGEM-T easy vector (Promega). Twenty-one clones of Patient 1, 44 clones of Patient 2, 39 clones of Patient 3, and 39 clones of Patient 4 were sequenced. The International ImMunoGeneTics information system (<http://imgt.cines.fr/>) was used to identify the V, D, and J segments and somatic mutations.²⁰ The ratio of replacement and silent mutations was determined for the framework regions and the complementarity-determining regions, and the distribution of replacement mutations in the framework regions was analyzed according to the binomial distribution model of Chang and Casali.²¹

Flow cytometry

Flowcytometric immunophenotyping of blood samples from four patients, nine relatives (including eight carriers), and eight controls was performed to evaluate markers and subgroups of B cells. We also analyzed bone marrow samples from Patient 1 and from five controls, as previously described.²² Antibodies against CD21 (LB21), CD81 (JS-81), and CD225 (Leu13) were used to further analyze the CD19-complex.^{15, 23}

Western blotting

B cells in blood were sorted from mononuclear cells with the use of the magnetic affinity cell-sorting B-cell purification kit (Miltenyi Biotec). Lysates of B cells (2×10^6) were separated by sodium dodecyl sulfate–polyacrylamide-gel electrophoresis and immunoblotted with the use of a polyclonal rabbit antiserum against the intracellular portion of human CD19.²⁴

Histology and immunohistochemistry

The biopsy specimen of a cervical lymph node from Patient 1 and the tonsil-biopsy specimen from Patient 2 were fixed in formalin, embedded in paraffin, and stained with hematoxylin and eosin. Immunohistochemistry was performed according to standard procedures involving monoclonal antibodies against CD20 (L26), CD21 (1F8), CD79a (JCB117), BCL-2 (124), BCL-6 (PG-B6p), and Ki67 (MIB-1), all obtained from DakoCytomation.

B-cell activation

Blood mononuclear cells were incubated with 6 μg of indo-1 per milliliter of cell suspension (molecular probes) to evaluate calcium fluxes after stimulation. Levels of free intracellular calcium were measured in CD20⁺ B cells with the use of flow cytometry in a FACSVantage station (BD Biosciences) before and after stimulation with *Staphylococcus aureus* Cowan I (Calbiochem) in a 1:500 dilution or with 20 μg of goat antihuman IgM F(ab')₂ per milliliter (Jackson ImmunoResearch Laboratories). Subsequently, 2 μg of ionomycin per milliliter (molecular probes) was added to control for intracellular loading of indo-1.

B-cell proliferation

Enriched blood B cells (1×10^5 per well) were cultured in 96-well flat-bottomed plates for 48 or 72 hours at 37°C and stimulated with *S. aureus* Cowan I in a 1:10,000 dilution or with 20 μg of anti-IgM F(ab')₂ per milliliter. Proliferation of the B cells was assessed by incorporating 0.5 μCi of [³H]thymidine in each well.

In vivo vaccination with rabies vaccine

Patients, relatives, and controls were vaccinated twice with the human diploid-cell rabies vaccine (Institut Pasteur Merieux, Merck Sharp & Dohme) according to standard protocols. Antibody levels and avidity were measured as previously described.²⁵

RESULTS

Identification of CD19 defects

Flowcytometric immunophenotyping with antibodies against the cell-surface markers CD3 (on T cells), CD16 or CD56 or both (on natural killer cells), and CD19 or CD20 (on B cells) results in the identification of more than 95 percent of lymphocytes. All four patients had normal absolute numbers of CD20⁺ B cells. In contrast, membrane expression of CD19 on B cells was not detectable in Patient 1 and was barely detectable in Patients 2, 3, and 4 (Figure 1A).

Sequencing of the *CD19* gene in Patient 1 revealed an insertion of an adenine in exon 6 of both alleles of *CD19*. This insertion causes a frame shift, and thus there is a premature stop codon at the intracellular amino acid 328 (Figure 1B). Patients 2, 3, and 4 were homozygous for a dinucleotide deletion of guanine and adenine in exon 11, resulting in a premature stop codon at the intracellular amino acid 465 (Figure 1B). Living parents and several members of both families carried one mutated allele (Figure 1C and 1D) but had no clinical features of immunodeficiency.

Normal levels of *CD19* transcripts were found in B cells from all patients (data not shown). Western blotting did not detect the CD19 protein in B cells from Patient 1, because the CD19 in this patient lacked most of the cytoplasmic domains. However, a reduction in intracellular levels of CD19 was observed in B cells from Patient 4 (data not shown), confirming the flowcytometric results.

Membrane expression of the CD19-complex

The level of expression of CD19 in the carriers of the mutations was lower than that in controls (Figure 2A). In addition, CD21 expression on the surface of patients' B cells was also reduced (Figure 2B). CD81 and CD225 molecules were expressed at normal levels by the B cells of all patients and carriers (data not shown).

B-cell differentiation

The precursor-B-cell compartment in the bone marrow of Patient 1 showed a normal relative distribution of all differentiation stages (data not shown).²² Igκ⁺ B cells and Igλ⁺ B cells were present in normal ratios in blood samples from all patients. Moreover, B cells from all four patients had normal expression of other membrane-bound molecules, including IgM, IgD, CD20, CD22, CD38, CD40, β2-microglobulin, and HLA-DR. However, all four patients had decreased levels of CD5⁺ B cells (8 to 12 percent) and CD27⁺ memory B cells (1 to 6 percent) in blood, as compared with levels in age-matched controls and carriers (19 to 41 percent for CD5⁺ and 17 to 28 percent for CD27⁺) (Figure 2C and 2D). Memory B cells that switched immunoglobulin class were CD27⁺IgD⁻, lacking IgM and IgD, and were present in decreased numbers in blood samples from all patients. Sequencing of the V_H-Cα and V_H-Cγ transcripts showed somatic hypermutations in a pattern suggesting the potential to produce an antigen-selected B-cell-receptor repertoire, which is a molecular sign of a response to antigenic stimulation (data not shown).

The numbers of CD27⁺ memory B cells in carriers in the family of Patient 1 were similar to those in controls, whereas carriers in the family of Patients 2, 3, and 4 had fewer memory

Figure 1. Mutations in the *CD19* gene.

Panel **A** shows the results of flowcytometric analysis of the membrane expression of CD19 on B cells in blood from the four patients and a control. B cells are shown in red; black represents non-B cells; both the x-axis and y-axis show a log (base-10) scale. Patient 1 showed a complete lack of CD19 on CD20⁺ blood B cells, and the three other patients had variable traces. Three CD19 monoclonal antibodies (SJ25C1, 4G7, and HIB19) and one CD20 monoclonal antibody (L27) were used. PerCP denotes peridinin chlorophyll protein, APC allophycocyanin, PE phycoerythrin, and FITC fluorescein isothiocyanate. Control B cells stained positive for both CD19 and CD20. Panel **B** shows the location of mutations in the *CD19* gene. Exons 1 through 14 code for CD19, which consists of two immunoglobulin-like domains (Ig1 and Ig2), a transmembrane domain (TM), and many cytoplasmic domains containing nine conserved tyrosines. Patient 1 had a homozygous insertion of an adenine in exon 6, resulting in three altered amino acids and a premature stop codon at position 328 of the protein. Patients 2, 3, and 4 had a homozygous dinucleotide deletion in exon 11, resulting in two altered amino acids and a premature stop codon at position 465. The premature stop codons lead to the deletion of part of the cytoplasmic domains, including the two tyrosine residues that are critical for signal transduction through CD19 (indicated with a large y in the diagram of the protein).²⁴ Panels **C** and **D** show the pedigrees of Patient 1 and Patients 2, 3, and 4, respectively. Half-solid symbols denote known carriers of the mutation, solid symbols family members who are homozygous for the mutation, symbols with a slash deceased members, squares male family members, circles female family members, and N family members who are known not to be carriers. The parents of Patient 1 were consanguineous. No consanguinity could be confirmed in the family of Patients 2, 3, and 4.

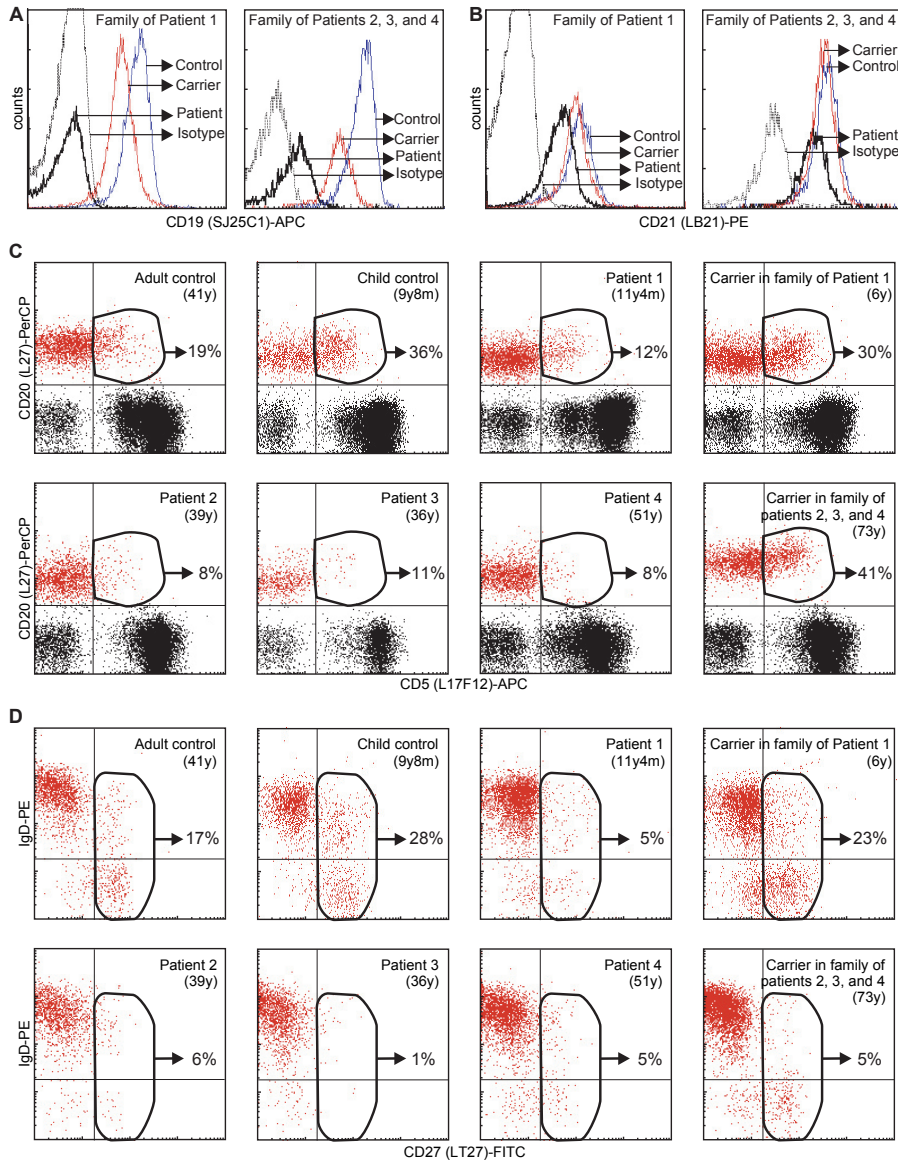

Figure 2. Immunophenotype of mature B cells in patients with a CD19 mutation.

All four patients had a reduced level of expression of CD19 or no expression on B cells in blood, as compared with levels in the controls and the mouse IgG1 isotype control (Panel A). In addition, the level of expression of CD19 on B cells in blood from carriers was lower than that in the controls. The level of expression of CD21 on B cells in blood from the patients was lower than that in carriers and controls (Panel B). The level of expression of CD5 on CD20⁺ B cells (shown in red; black represents non-B cells) was decreased in all patients as compared with carriers and controls, whereas it was normal on CD20⁻ cells (Panel C; log scale). The level of expression of CD27⁺IgD⁺ and CD27⁺IgD⁻ memory B cells was lower in the patients than in age-matched controls (Panel D; log scale). PerCP denotes peridinin chlorophyll protein, APC allophycocyanin, PE phycoerythrin, and FITC fluorescein isothiocyanate.

B cells than controls (Figure 2D). In general, however, in contrast to the patients, the carriers in the family of Patients 2, 3, and 4 had mainly memory B cells that had switched immunoglobulin class and normal serum immunoglobulin levels (data not shown).

Germinal centers in secondary lymphoid organs

Histologic analysis of a sample of cervical lymph node from Patient 1 showed multiple B-cell follicles of small-to-moderate size with proliferation centers on immunohistochemical staining for CD79a, BCL-2, BCL-6, CD21, and Ki67 (Figure 3A). Follicles of normal size and architecture were also found in the tonsil specimen from Patient 2 (Figure 3B).

Calcium mobilization and proliferation on stimulation of the B-cell receptor

B-cell receptor-mediated activation causes an initial flux of calcium from the rough endoplasmic reticulum into the cytoplasm, followed by a sustained influx of extracellular calcium.²⁶ As compared with control B cells, the B cells from all four patients with CD19 deficiency exhibited defective calcium fluxes after stimulation with an anti-IgM antibody, which cross-links IgM molecules on the B-cell surface. No calcium influx or efflux was observed in the B cells from Patient 1, whereas the initial calcium influx was delayed in B cells from Patients 2, 3, and 4. Furthermore, calcium efflux in all four patients was delayed and remained low for the duration of the experiment (Figure 4A; data for Patients 2 and 3 not shown). B cells from heterozygous relatives had normal calcium fluxes (data not shown). Normal calcium fluxes were found in Patients 2, 3, and 4 in response to *S. aureus* Cowan I, which activates B cells by means of innate immune receptors and the B-cell receptor (data not shown).

B cells from Patient 1 proliferated poorly after stimulation with *S. aureus* Cowan I or an anti-IgM antibody, as compared with B cells from the control (Figure 4B). B cells from the parents of Patient 1, who are carriers of the mutation, showed intermediate proliferation in response to both *S. aureus* Cowan I and anti-IgM antibody (Figure 4B). B cells from carriers in the family of Patients 2, 3, and 4 proliferated normally after stimulation with *S. aureus* Cowan I or anti-IgM antibody (not shown).

Antibody response to rabies vaccine

To test the primary and secondary antibody responses *in vivo*, all patients were vaccinated twice with rabies vaccine (at week 0 and week 13). The primary response of production of IgG anti-rabies antibody in Patient 1 was low but detectable, whereas Patients 2, 3, and 4 did produce IgG anti-rabies antibodies after the first vaccination. The secondary IgG response, after week 13, in all patients was below the 95 percent confidence interval of the normal response (Figure 4C).²⁵ Furthermore, no increase in avidity was observed in Patient 2, 3, or 4, and Patient 1 had only a marginal increase in avidity during the secondary response (Figure 4D). The second antibody response and the increase in avidity maturation were normal in the two carriers evaluated in the family of Patients 2, 3, and 4 (Figure 4C and 4D).

DISCUSSION

We described four patients (from two different families) with homozygous mutations in *CD19* and showed that their profound hypogammaglobulinemia resulted from a poor response to antigen by mature B cells. Both CD19 mutations were frameshift mutations, causing premature stop codons that result in the deletion of the total cytoplasmic domain (in the family of Patient 1) or a major part of the cytoplasmic domain (in family B). Both truncations result in the lack of the three C-terminal tyrosine residues, two of which have been shown to be critical for signal transduction through CD19 (Figure 1B).²⁴

These mutations are not likely to be polymorphisms; CD19 is the most broadly used B-cell marker for flowcytometric immunophenotyping of lymphocytes and has not been found to be lacking in large-scale studies of healthy children.^{27, 28} Moreover, the B cells of heterozygous carriers of the mutation expressed CD19, albeit at slightly lower levels than noncarriers. Furthermore, CD19 - together with CD21, CD81, and CD225 - forms a signaling complex that decreases the threshold for the activation of B cells as mediated by the B-cell receptor.²⁹

B cells from CD81-knockout mice have decreased CD19 expression.^{30, 31} The mature B cells from our patients, however, had a normal level of expression of CD81 and CD225 but a reduced level of expression of CD21, suggesting a dependency of CD21 on CD19. Normal levels of *CD19* transcripts in the B cells of these patients indicate that the reduction in the level of the protein does not result from nonsense-mediated decay of mRNA, but rather from the instability of the truncated CD19 proteins. This interpretation is consistent with the observation that truncated (but otherwise stable) CD19 molecules can associate with CD81 and CD225 on the membranes of B cells in which 95 percent of the cytoplasmic domains of CD19 are deleted.³²

The CD19 deficiency did not disturb the differentiation of precursor-B cells in the bone marrow. Still, CD19-deficient B cells may undergo differentiation less efficiently than CD19⁺ B cells, as has been observed in CD19-knockout mice.^{33, 34} Nevertheless, our patients had normal numbers of mature B cells in blood.

The numbers of CD5⁺ B cells in our patients were decreased, as they are in CD19-knockout mice.^{35, 36} CD5 is a negative regulator of B-cell receptor signaling, and in mice, this marker defines the subgroup of autoreactive B-1a cells.^{37, 38} It is likely that, in our patients, the inhibitory effect of CD5 on B-cell-receptor signaling is superfluous in the absence of CD19.

The numbers of CD27⁺IgD⁺ and CD27⁺IgD⁻ memory B cells in blood from all four patients were decreased. Together with the finding of decreased serum immunoglobulin levels, this finding suggests that terminal differentiation of B cells into memory B cells and plasma cells is affected. In two patients, secondary lymphoid tissues contained follicles of small-to-moderate size with germinal centers that appeared normal. CD19-knockout mice lack germinal centers, but centers appear when the animals are challenged with live virus.³⁹ IgG antibodies and circulating memory B cells are defective in these mice,³⁹ as they are in our four patients.

IgG and IgA transcripts with antigen-driven hypermutation were found in our patients at variable levels, indicating that CD19-deficient B cells are in principle able to undergo antigen-dependent differentiation, albeit with reduced efficiency. In mice, defects in CD19 signaling due to mutations in critical intracellular tyrosines result in the absence of high-affinity antibodies owing to low B-cell proliferation and abnormal immunoglobulin-class switching.^{24, 40, 41}

Figure 3. Normal formation of the germinal center.

Panel **A** shows cross sections of a cervical lymph node from Patient 1 with secondary lymphoid follicles of small-to-moderate size. The whole lymph node was stained with hematoxylin and eosin (top section) and CD79a (second section). The dense light-blue areas of CD79a-negative cells consisted mainly of T cells, as observed on staining with CD3 (not shown). The follicles containing B cells are shown (bottom four sections) after staining with monoclonal antibodies against CD21, BCL-2, BCL-6, and Ki67. The germinal centers consist of BCL-2⁺BCL-6⁺ B cells, proliferating in a network of CD21⁺ follicular dendritic cells. The proliferation marker Ki67 distinguishes dark and light areas, with the number of cycling cells greater in the germinal center. Panel **B** shows a sample of a tonsil from Patient 2, stained with hematoxylin and eosin (top section) or with monoclonal antibodies against CD79a (second section), BCL-2 (third section), or Ki67 (bottom section). The germinal centers consist of CD79a⁺BCL-2⁺ B cells, with Ki67-positive cycling cells.

The inefficient response of CD19-deficient B cells in these patients probably results from the loss of dual antigen recognition through the B-cell receptor and the CD19-complex.^{15, 42} The B cells from all four patients had abnormal calcium fluxes on stimulation, but the differences between Patient 1 and the other three patients may be due to the presence of different mutations. Patient 1 lacked all the intracellular domains responsible for signal transduction³²; in Patients 2, 3, and 4, the CD19 molecule lacked only 92 amino acids at the intracellular C-terminal end, which contains two critical tyrosines that are required for most functions of CD19.²⁴ Most of the intracellular domains were present, potentially permitting some B-cell signaling.⁴³ Nevertheless, all four patients with CD19 deficiency had substantially decreased antibody responses (levels and avidity) after vaccination with rabies vaccine. We conclude that the CD19 signals that normally enable B-cell responses to antigenic stimuli are lacking in our patients.

This study shows that the disruption of CD19 signaling results in a primary antibody deficiency, mainly characterized by a poor antigen-specific response. On the basis of the crucial role of CD19 in signaling by the B-cell receptor on antigen recognition, it is likely that defects in other members of the CD19-complex (CD21, CD81, and CD225) also lead to antibody deficiency in humans.

ACKNOWLEDGEMENTS

We are indebted to Mrs. B.H. Barendregt, Mrs. S. de Bruin-Versteeg, and Mr. E.F.E. de Haas for their support with flowcytometric immunophenotyping and functional assays; to S. Evans, Rockwell Park Institute, for the antihuman CD225; to R. Carter, University of Alabama at Birmingham, for the polyclonal rabbit anti-CD19 antiserum; to Mrs. C.M. Jolvan der Zijde for performing the serologic antirabies response experiments; to Ms. C. Rubeles and Mrs. B. Vieco, Dr. C. Montoya, Dr. M. Schlesier, Dr. U. Salzer, and Mrs. D. Thiel for their technical assistance; to Dr. H. Arbag and Dr. M. Cihat Avunduk for their support in the diagnostic procedures; and to Mrs. W.M. Comans-Bitter for assistance with the figures.

DISCLOSURES

Supported by grants from Sophia Kinderziekenhuis Fonds (349), Revolving Fund 2000, the Vereniging Trustfonds Erasmus Universiteit Rotterdam, the Colombian Institute for Scientific and Technological Development (Colciencias; 1115-04-11924 and 1115-05-16874), and the Deutsche Forschungsgemeinschaft (GR1617/3 and SFB620). No potential conflict of interest relevant to this article was reported.

Figure 4 (facing page). In vitro responses of B cells and antibody responses to rabies vaccine.

The stimulation of blood mononuclear cells with anti-IgM antibody did not result in an initial calcium influx in CD20⁺ B cells from Patient 1 and resulted in a delayed initial calcium influx in cells from Patient 4, as compared with the control cells (Panel A; the dashed line indicates the peak of the initial calcium influx in the control). In Patient 4, the subsequent calcium flux was sustained and relatively high. No defect in calcium flux was seen in carriers of the CD19 mutation (not shown). Ionomycin was added as a control for intracellular loading of indo-1. The proliferation of B cells from Patient 1 was less than that in two carriers and a control from her family after stimulation with *Staphylococcus aureus* Cowan I (SAC) or anti-IgM antibody (Panel B). The blood B cells were harvested and cultured for 48 or 72 hours in medium alone or medium with either SAC or anti-IgM antibody. The proliferation index is the ratio of the counts per minute of stimulated and unstimulated B cells. Each experiment was performed in triplicate, and T bars represent standard errors. The levels of anti-rabies IgG antibodies were subnormal in the four patients after an initial vaccination at week 0 (arrow) and a booster vaccination at week 13 (arrowhead) (Panel C). The relative avidity index of the antibody was also low in these patients (Panel D). These patients were compared with 18 controls vaccinated according to the same methods;²⁵ the gray area represents the 95 percent confidence interval of the anti-rabies IgG level and avidity index. Two carriers from the family of Patients 2, 3, and 4 were also tested and had a normal quantitative and qualitative response. NaSCN denotes sodium thiocyanate.

ABSTRACT

The contribution of proliferation to B-lymphocyte homeostasis and antigen responses is largely unknown. We quantified the replication history of mouse and human B-lymphocyte subsets by calculating the ratio between genomic coding joints and signal joints on kappa-deleting recombination excision circles (KREC) of the *IGK*-deleting rearrangement. This approach was validated with *in vitro* proliferation studies. We demonstrate that naive mature B lymphocytes, but not transitional B lymphocytes, undergo *in vivo* homeostatic proliferation in the absence of somatic mutations in the periphery. T-cell dependent B-cell proliferation was substantially higher and showed higher frequencies of somatic hypermutation than T-cell independent responses, fitting with the robustness and high affinity of T-cell dependent antibody responses. More extensive proliferation and somatic hypermutation in antigen-experienced B lymphocytes from human adults compared to children indicated consecutive responses upon additional antigen exposures. Our combined observations unravel the contribution of proliferation to both B-lymphocyte homeostasis and antigen-induced B-cell expansion. We propose an important role for both processes in humoral immunity. These new insights will support the understanding of peripheral B-cell regeneration after hematopoietic stem cell transplantation or B cell-directed antibody therapy, and the identification of defects in homeostatic or antigen-induced B-cell proliferation in patients with common variable immunodeficiency or another antibody deficiency.

B-cell development, V(D)J recombination, B-cell memory, Homeostatic Proliferation, KREC.

INTRODUCTION

B lymphocytes appear in peripheral blood and secondary lymphoid organs after they have differentiated from precursor B cells in bone marrow¹ and have created a unique B-cell antigen receptor by V(D)J rearrangement of their Ig heavy and Ig light chain loci.² In the periphery, multiple B-cell subsets can be identified, which are either naive or have been exposed to antigen.

The mouse spleen has been extensively studied for B-cell maturation (for review see reference 3). Although several models exist,^{4, 5} the general consensus is that recent bone marrow emigrants are AA4.1⁺ and defined as transitional B cells. Subsequently, these cells can give rise to either naive follicular B cells, or marginal zone (MZ) B cells, which are named based on their anatomical location. MZ B cells show a rapid and predominantly

T-cell independent response to pathogens, whereas follicular B cells show a T-cell dependent response in a germinal center reaction, where they undergo somatic hypermutation (SHM) and class-switch recombination (CSR) to generate an optimized high affinity antibody response.

In man, the recent bone marrow emigrants, i.e., the transitional B lymphocytes, are CD38⁺CD24⁺IgD⁺ and represent a relatively small subset compared with the CD38⁻IgM⁺IgD⁺CD27⁻ naive mature B lymphocytes in blood and peripheral lymphoid organs.^{6, 7} In peripheral blood, a substantial fraction of the naive B-lymphocyte population expresses the CD5 antigen and is prone to produce polyreactive antibodies.⁸ Splenic MZ B lymphocytes in man are IgM⁺IgD⁺CD27⁺. They show a rapid IgM response to blood-borne T-cell independent antigens,^{9, 10} and their Ig loci carry somatic mutations.¹¹ Counterparts of splenic MZ B lymphocytes are found in lymph nodes, tonsils, and Peyer's patches, and they circulate in blood.¹²⁻¹⁵ Because these cells are not anatomically located in the splenic MZ, it was suggested to refer to them as natural effector B lymphocytes.¹⁶ T-cell dependent responsive B lymphocytes proliferate in a germinal center reaction as centroblasts (CD38⁺CD77⁻IgD⁻) (for review see reference 17). These centroblasts undergo SHM before further differentiation into centrocytes (CD38⁺CD77⁻IgD⁻), which are subsequently selected based on the highest affinity for their cognate antigen, undergo CSR, and give rise to either CD27⁺ memory B lymphocytes or CD38^{hi} antibody-producing plasma cells.¹⁸ B-cell proliferation upon antigen encounter in the germinal center is a key step in the humoral immune response, which has been extensively studied,^{19, 20} but the extent of antigen-induced proliferation of B lymphocytes remains largely unknown.

Recent reports suggest that in addition to antigen-induced proliferation, naive B lymphocytes can proliferate without further differentiation.²¹⁻²³ This homeostatic proliferation of naive B lymphocytes has been described in mouse models in response to a B-cell deficit.²² Theoretically, the absolute number of naive B lymphocytes is regulated by four processes: (a) output from bone marrow; (b) survival; (c) loss of naive B lymphocytes via further maturation after antigen encounter;²⁴ and (d) antigen-independent (homeostatic) proliferation. However, similar to the extent of antigen-induced B-cell proliferation, it remains unclear to what extent proliferation contributes to naive B-lymphocyte numbers; to answer both questions, a robust assay is needed to assess the replication history of B cells.

Here we introduce the use of kappa-deleting recombination excision circles (KRECs)

Figure 1. Detection of coding joints and signal joints of kappa-deleting rearrangements in mice (A) and man (B). V(D)J recombination on the *IGK* locus results in a V_κ-J_κ coding joint. Subsequent rearrangement between the IRS1 (mouse) or intronRSS (human) and the RS (mouse) and Kde (human) elements can make the *IGK* allele nonfunctional by deleting the C_κ exons and the enhancers. Consequently, the coding joint precludes any further rearrangements in the *IGK* locus and therefore remains present in the genome. The KREC with the corresponding signal joint is a stable double-stranded, circular DNA structure. The coding joint in the genome and the signal joint on the episomal excision circle can be quantified via RQ-PCR using the indicated primers and TaqMan probes. The murine *IGK* locus contains two intronRSS sequences, IRS1 and IRS2, of which IRS1 has the most conserved RSS sequence and is >10-fold more frequently found in rearrangements to RS (reference 62 and unpublished data).

to determine the replication history of both human and mouse mature B-cell subsets. Rearrangement of the J κ -C κ intron recombination signal sequence (IRS1 in mouse and intronRSS in man) to the kappa-deleting element (RS in mouse and Kde in man) renders the *IGK* locus nonfunctional, precludes any further rearrangements in the *IGK* locus, and therefore the coding joint of this rearrangement remains stably present in the genome (Figure 1, A and B).^{25, 26} It is a common rearrangement because it is present in 30 % of Ig κ ⁺ and in almost all Ig λ ⁺ mature human B lymphocytes and does not influence antigen specificity.^{27, 28} The chromosomal DNA located in between the two rearranging elements is excised from the genome and circularized into stable episomal structures, which are diluted twofold by each cell division (Figure 2A).²⁹⁻³² Previously, we demonstrated the use of T-cell receptor excision circles (TRECs) for studying rearrangement and proliferation processes.^{30, 31} Subsequently, TRECs of δ REC- ψ J α rearrangements have been used as markers for recent thymic emigrants and T-cell expansion in patients treated for HIV infection.^{33, 35}

In this study, we introduce the use of KRECs to accurately assess the replication history of isolated mouse and human B-cell subsets. Using this approach we demonstrate homeostatic proliferation of mature B lymphocytes, but not of transitional B lymphocytes, in healthy individuals. Furthermore, mouse MZ and human natural effector B lymphocytes, which mainly respond to T-cell independent antigens, undergo additional antigen-induced proliferation. The T-cell dependent antigen response in the germinal center was found to be much stronger with regard to both proliferation and SHM.

RESULTS

The KREC assay is a robust technique to determine the replication history of B cells

The ratio between the kappa-deleting rearrangement and the corresponding excision circle can be used as measure for the *in vivo* replication history of an isolated B-cell subset, assuming that the excision circle is a stable DNA structure, which is diluted twofold in every cell division (Figure 2A). Consequently, real-time quantitative (RQ)-PCR assays were designed for detection of the coding joints and the corresponding signal joints of both the mouse IRS1-RS (Figure 1A) and the human intronRSS-Kde (Figure 1B) rearrangements. The two mouse RQ-PCR assays were tested for equal efficiency on serial dilutions of constructs containing either the coding joint or the signal joint. To minimize the chance of contamination in potential future clinical studies, a special cell line control was created for the human KREC studies. The Ig κ ⁺ B-cell line U698-M was selected because it has two V κ -J κ -rearranged *IGK* alleles, one of which is out-of-frame and contains an intronRSS-Kde rearrangement (Figure 3, A and B). To obtain an equal ratio between the intronRSS-Kde coding and signal joints, an intronRSS-Kde signal joint construct was inserted into the genome of the U698-M cell line using retroviral transduction. Individual clones were sorted, and Southern blot analysis revealed a single insertion per genome for three clones: DB01, DB11, and DE09 (Figure 3B). Each of these stable B-cell lines contained both the coding joint and the corresponding signal joint of the intronRSS-Kde rearrangement and were therefore used as positive control for assessment of the efficiency of both human RQ-PCR assays.

The stability and twofold dilution of excision circles were investigated by *in vitro*

proliferation experiments. Resting B lymphocytes were isolated from wild-type mouse spleen, labeled with CFSE, and cultured with IL-4, LPS, and anti-IgM for 2-3 d. DNA was isolated from B cells before culture and from sorted B cells that had undergone 1, 2, 3, or 4 cell divisions to quantify the kappa-deleting rearrangement and the excision circle. The combined data from three individual experiments show that resting B lymphocytes contain a coding joint to signal joint ratio of 1:1 ($\Delta C_T = 0$). Furthermore, the ΔC_T ($C_{T_{\text{coding joint}}} - C_{T_{\text{signal joint}}}$) of the RQ-PCRs corresponded well with the number of cell divisions these cells underwent in culture as observed with CFSE staining (Figure 2B). Therefore, the KREC assay can be used as a robust technique to determine the replication history of B-cell subsets *in vitro*.

In vivo replication history of mouse B-cell subsets

To determine the *in vivo* replication history using the KREC assay in a well-defined system, mouse B-cell subsets (B220⁺) from spleen and Peyer’s patches were isolated (Figure 4A).

Figure 2. Quantification of the replication history of B cells using KRECs.

A. When a B lymphocyte with an intronRSS–Kde rearrangement divides, both daughter cells inherit the intronRSS–Kde coding joint in the genome. However, the signal joint, which is on the episomal KREC, will be inherited by only one of the two daughter cells. Crucially, the ΔC_T of the PCRs detecting the coding joint and the signal joint exactly represent the number of cell divisions a B lymphocyte has undergone because both processes have an exponential increase with base number 2. **B.** The ΔC_T between the coding joint and the signal joint is shown for mouse splenic B cells that were cultured *in vitro* with polyclonal stimulation and were sorted based on the CFSE staining intensity as measure for 0, 1, 2, 3, and 4 cell divisions.

Figure 3. Generation of a human control B-cell line with one intronRSS–Kde coding joint and one artificially introduced signal joint per genome.

A. Schematic representation of the Southern blot probes that recognize the *IGK* alleles of the U698-M cell line and the KREC signal joint construct that was introduced into the cell line. The Kde probe recognizes both *IGK* alleles, whereas the Kde-RSS probe recognizes allele 1, which does not harbor an intronRSS–Kde rearrangement, and the KREC construct. **B.** Southern blot of the original U698-M cell line and three single clones that contain a unique insertion of the signal joint construct.

From spleen, T1 (AA4.1⁺CD23⁻) and T2 (AA4.1⁺CD23⁺) transitional B cells and naive follicular (AA4.1⁻CD21^{low}CD23^{hi}) and MZ (AA4.1⁻CD21^{hi}CD23^{low}) B lymphocytes were purified, whereas IgA⁺ class-switched B lymphocytes were isolated from Peyer's patches. Total bone marrow samples were used to determine the replication history of precursor B cells, in which the Ig κ -deleting rearrangement is initiated (Figure 4A).

Precursor-B cells in bone marrow and transitional B cells in spleen did not show replication (Figure 4B). In contrast, naive follicular B cells showed limited proliferation (1 cell division). MZ B cells and class-switched IgA⁺ B cells showed a more extensive replication history of 4 and 5.5 cell divisions, respectively. As expected, the observed replication histories increased with more progressive differentiation stages. Consequently, the KREC assay is a powerful tool to study not only the *in vitro* replication history but also the *in vivo* replication history of sorted B-cell subsets.

The extent of antigen-induced B-cell proliferation in man

The majority of the intronRSS–Kde rearrangements in man is initiated in small pre-B-II cells.²⁷ Therefore, B-cell subsets starting with the small pre-B-II stage were isolated from bone marrow, tonsil, and peripheral blood using previously established markers (Figure 5A and Figure 6A) to quantify intronRSS–Kde coding joints in the genome and the intronRSS–Kde signal joints on the KRECs.^{6, 15, 18, 27, 36} The coding joints were easily detected; 35–50 % of the alleles in all peripheral B-cell subsets carried this rearrangement (not depicted). In small pre-B-II and immature B cells the ΔC_T was 0.4 (Figure 5B). This indicates that

precursor-B cells in human bone marrow hardly proliferate after rearrangement of intronRSS to Kde.

Transitional B lymphocytes in tonsil did not show replication, whereas naive mature B lymphocytes in tonsil showed a replication history of 2.5 cell divisions (Figure 5B), indicating a substantial proliferation in this subset. Natural effector B lymphocytes (counterparts of splenic MZ B lymphocytes) underwent more proliferation: on average 4.1 cell divisions. Centroblasts and centrocytes in the germinal center, memory B cells, and plasma cells all showed a replication history of 8 cell divisions. As expected by their nature,

Figure 4. Replication history of mouse B-cell subsets.

A. Scheme of the differentiation stages of mature B-cell development in mice. B-cell subsets were isolated based on the indicated marker expression from spleen and Peyer's patches. **B.** The replication history of each B-cell subset. The ΔC_T between the coding joint and the signal joint PCRs represents the number of cell divisions, which are given for each subset. The data are the means of three independent sorts and are presented as mean \pm SD.

the centroblasts in human tonsil form the major proliferative subset. It can thus be concluded that naive mature B lymphocytes have already proliferated but massive proliferation is found in subsequent germinal center reactions where each cell generates 45 ($2^{[8-2.5]}$) or more daughter cells. Several mature B-lymphocyte subsets circulate in blood and can be identified as counterparts of subsets found in secondary lymphoid organs (Figure 6A). The four main human B-lymphocyte subsets were isolated from blood of healthy adults and analyzed for their replication history. Naive CD5⁻ B lymphocytes in adult peripheral blood were found to have a replication history of 1.9 (Figure 6B), which is almost similar to the total bulk of naive mature B lymphocytes in tonsils from children. Furthermore, natural effector B lymphocytes and memory B lymphocytes in adult blood were found to have a replication history of 5.6 and 10.9 cell divisions, respectively. For both populations, these

Figure 5. Replication history of human B-lymphocyte subsets from childhood tonsil.

A. Scheme of the differentiation stages of mature B-cell development. The B-cell subsets that contain the intronRSS-Kde rearrangement were isolated from bone marrow and tonsil samples of young children using the indicated markers. **B.** The replication history of each B-cell subset. The ΔC_T between the coding joint and the signal joint PCRs, which represents the number of cell divisions is given for each subset. The data are the means of independently sorted subsets from three children and are presented as mean \pm SD.

Figure 6. Replication history of the four main B-lymphocyte subsets in adult peripheral blood.

A. Schematic overview of the four main blood B-lymphocyte subsets and the markers that were used to isolate them from adult peripheral blood. **B.** The replication history of these subsets was determined as the ΔC_T of the coding joint and the signal joint PCR of subsets isolated from four or five donor samples (represented as mean \pm SD).

numbers are higher than what was found in childhood tonsil. This indicates that most memory B lymphocytes in adults have been exposed to their cognate antigen multiple times and have accordingly undergone additional proliferation in consecutive germinal center reactions.

The fourth major population isolated from blood was the CD5⁺ naive B-lymphocyte subset. This subset had a replication history of 0.4, similar to small pre-B-II cells and immature B cells in bone marrow and transitional B lymphocytes in tonsil. Thus, contrary to CD5⁻ naive mature B lymphocytes, CD5⁺ naive B lymphocytes do not proliferate in the peripheral B-cell compartment.

Naive B lymphocytes undergo homeostatic proliferation in healthy individuals

Using the KREC assay, we found that the mature B-lymphocyte subsets, except for the CD5⁺ naive B lymphocytes, had undergone proliferation in the periphery. Antigen-induced proliferation is usually accompanied by the induction of SHM. To provide a quantitative measurement for the presence of SHM, we determined the presence of mutations in a hot-spot motif in rearranged *IGK* (V κ -J κ) alleles involving the V κ 3-20 gene segment using a modified version of the Ig κ restriction enzyme-based hot-spot mutation assay (Ig κ REHMA; Figure 7, A–C).³⁷

Neither transitional and naive mature B lymphocytes from tonsil, nor CD5⁺ and CD5⁻ naive B lymphocytes from blood carried mutated V κ 3-20 to J κ rearrangements (<1.5 %; Figure 7, D and E). In contrast, germinal center and memory B-lymphocyte subsets contained

Figure 7. Quantification of SHM in human B-cell subsets.

The Ig κ REHMA assay was modified from Andersen et al. for use on genomic DNA.³⁷ **A**. Schematic representation of a V κ 3-20 to J κ rearrangement on genomic DNA. The V κ 3-20 gene segment contains two Fnu4HI restriction sites in a SHM hot-spot in the CDR1 region. In addition, a KpnI site is located downstream of the Fnu4HI sites in the FR2 region. V κ 3-20–J κ rearrangements were PCR amplified with one HEX-labeled V κ 3-20-intron forward and two J κ reverse primers that recognize all five J κ gene segments.⁶¹ Digestion of these PCR products with both Fnu4HI and KpnI resulted in unmutated fragments of 244 and 247 bp and mutated fragments of 262 bp. **B and C**. Spectratyping of V κ 3-20–J κ rearrangements of CD5⁺ B lymphocytes and memory B lymphocytes after double digest with Fnu4HI and KpnI. CD5⁺ B lymphocytes did not have a replication history and showed no SHM, whereas memory B lymphocytes in adult blood had undergone 11 cell cycles in the periphery and showed 30 % mutated V κ 3-20–J κ rearrangements. **D and E**. The percentage of mutated V κ 3-20–J κ rearrangements was measured in the same DNA samples that were previously used for determining the replication history (data represent means \pm SD).

substantial numbers of mutated V κ 3-20 alleles. Of the rearranged V κ 3-20 alleles, 7.5 % was mutated in natural effector B lymphocytes from childhood tonsil, and 16 % in natural effector B lymphocytes from adult blood. Centroblasts and centrocytes from childhood tonsil showed 9 % and 12 % mutated rearranged V κ 3-20 alleles, respectively. Memory B lymphocytes from childhood tonsil had 24 % mutated alleles, and memory B lymphocytes from adult blood had 30 % mutated alleles. Finally, plasma cells in childhood tonsil showed 14 % mutated alleles.

It can thus be concluded that naive mature B lymphocytes in blood and tonsil undergo limited proliferation in the absence of SHM, indicative of antigen-independent homeostatic proliferation. In contrast, the proliferation of centroblasts in tonsil is associated with SHM. The frequency of mutated alleles was higher in centrocytes, memory B cells, and plasma cells, probably as the result of selection for antigen binding. Finally, the frequency of mutated alleles is higher in adult natural effector B lymphocytes and memory B lymphocytes than in their counterparts isolated from tonsils of children. This correlated with the higher proliferation rate, fitting with additional antigen-induced proliferation and SHM in adults.

DISCUSSION

In this study, we demonstrate the contribution of proliferation to B-cell homeostasis and the extent of antigen-induced B-cell expansion in mouse and man. Assessment of the replication history and the SHM status allowed us to discriminate homeostatic proliferation from antigen-induced proliferation. The homeostatic proliferation in naive B lymphocytes did not differ between human childhood and adult naive B lymphocytes, whereas the extensive proliferation and SHM of natural effector and memory B cells in adults was greater than in children, indicating additional antigen encounters in adults.

In our novel RQ-PCR-based KREC assay, we use the coding joint versus signal joint ratio of the intronRSS–Kde rearrangement to obtain highly accurate quantification of the replication history of mature B lymphocytes. This approach differs from studies in which the kinetics of the peripheral B-cell pool was assessed with BrdU or 6,6-²H₂-glucose.^{38, 39} The latter studies have provided insight into the recent turnover of B-cell subsets but could not quantify the contribution of proliferation to B-cell homeostasis. Because of time-lapse differences (measurement 3-4 d after deuterium glucose infusion) it was not possible to determine whether proliferation occurred in the investigated B-cell differentiation stage or in an earlier (preceding) differentiation stage.³⁹ The KREC assay allows us to assess the total number of cell divisions that B cells, in a well-defined subset isolated from lymphoid tissue, have undergone since their emigration from bone marrow. Consequently, differences in replication history between B-cell subsets can be straightforwardly assessed by measuring the KREC content of the B-cell subsets under study.

The applicability of KRECs depends on their stability, which has been suggested before but never formally proven.²⁹ In theory, the excision circles can be subject to transcriptional activity and recombinase activity in precursor-B cells because of the presence of *IGK* enhancers. Furthermore, it is unclear whether excision circles remain stably present in the nucleus of one of the two daughter cells after cell division. We show here that there is very little or no breakdown of KRECs in precursor-B cells and that the KREC content is diluted twofold with every cell division.

The use of KRECs to measure the replication history of B-cell subsets is analogous to the use of δ REC- ψ Ja rearrangements and their corresponding TRECs to study T-cell dynamics. Although the use of TRECs provided insight into the effects of novel antiviral therapies on the thymic output in patients with HIV infection,^{33,34} TRECs could not be used to quantify proliferation because most δ REC- ψ Ja coding joints are deleted from the genome by subsequent V α -Ja rearrangements.^{30,31} Therefore, TREC data as measured in T lymphocytes of healthy and diseased individuals are difficult to interpret.^{31,35} Our KREC assay does not have these limitations. In contrast, the intronRSS-Kde rearrangement has several advantages for studying the replication history of B lymphocytes: (a) it is a frequently occurring *IGK* gene rearrangement in both normal and malignant B cells;^{27,28} (b) it is one of the last Ig gene rearrangements in bone marrow-derived B cells before obtaining a functional Ig molecule,²⁷ ensuring that the corresponding KRECs are abundantly present in naive B lymphocytes; (c) it is a single-step rearrangement, which allows easy design of RQ-PCR primers and probes for accurate detection of the coding joints and signal joints;⁴⁰ and (d) it is an end-stage rearrangement, precluding further rearrangements,⁴¹ which implies that the coding joint is retained in the genome while the corresponding signal joint on the KREC is diluted twofold by each cell division. These characteristics make the intronRSS-Kde rearrangement a solid RQ-PCR target for accurate quantification of mature B-lymphocyte proliferation.

The intronRSS-Kde rearrangement is initiated in precursor-B cells in bone marrow and is frequently found to inactivate functionally rearranged *IGK* loci, suggesting actively induced receptor editing in bone marrow.⁴² Furthermore, receptor revision has been speculated to occur in peripheral B lymphocytes, based on low levels of *RAG* gene transcription and the presence of double-stranded DNA breaks in J κ gene segments.⁴³⁻⁴⁸ If intronRSS-Kde rearrangements would be induced in the process of receptor revision in peripheral B lymphocytes, the observed number of cell divisions measured with KRECs should be an underestimate. However, because the *RAG* mRNA and double-stranded DNA break levels are clearly lower in peripheral B-cell subsets compared with bone marrow and *RAG* expression is inhibited by BCR signaling,^{49,50} the influence of receptor revision on measuring proliferation using KRECs will be limited.

The contribution of proliferation to B-lymphocyte homeostasis in healthy individuals has never been shown. Using the KREC assay we were able to address this issue. We found no replication history for transitional B lymphocytes in mouse spleen and childhood tonsil. In addition, no replication was seen in the CD5⁺ B-cell subset in human peripheral blood. Recently, it has been shown that nearly all human transitional B cells express CD5, whereas only a fraction of the naive mature B lymphocytes express CD5.⁷ Thus, the CD5⁺ B-lymphocyte subset we isolated from peripheral blood mainly consists of transitional B lymphocytes. Consequently, the limited proliferation seen in CD5⁺ B lymphocytes is likely to be caused by the high abundance of excision circles from transitional B lymphocytes. Therefore, it remains unclear whether the absence of proliferation in the CD5⁺ B-cell subset reflects a difference in maturation stage or is a direct effect of CD5 expression.

Naive follicular B lymphocytes in mice and naive mature B lymphocytes obtained from human blood and tonsil showed proliferation in the absence of SHM. By definition, this is homeostatic proliferation, which occurred in the periphery, because no replication history was found for precursor-B cells and transitional B lymphocytes. Homeostatic proliferation has been observed before in naive T and NK cells.⁵¹⁻⁵⁴ It has been suggested to occur in B lymphocytes

also,²³ but it was only observed in response to a B-cell deficit.^{21, 22} Our results show for the first time that homeostatic proliferation of naive mature B lymphocytes occurs in healthy individuals and contributes greatly to the homeostasis of absolute B-lymphocyte numbers by two- to fourfold expansion of the naive B-lymphocyte pool. The factors driving this homeostatic proliferation need to be identified in future studies.

Splenic MZ B lymphocytes in mice showed more replications than naive follicular B lymphocytes. In absence of B-cell influx from bone marrow, MZ B lymphocytes persist much longer than naive follicular B lymphocytes.⁵⁵ Our results support earlier suggestions that this persistence partly results from an increased proliferation capacity. It remains unclear, however, whether this proliferation is antigen induced, especially because these cells carry nonmutated Ig genes.¹⁰ In contrast, human MZ B lymphocytes have a memory phenotype (CD27⁺) and carry mutated Ig genes generated mainly in response to T-cell independent antigens.^{9, 10, 15} We found that the replication history of their counterparts in childhood tonsil, natural effector B lymphocytes, was comparable to that of mouse MZ B lymphocytes. Studies in children younger than 2 yr suggest that natural effector B lymphocytes undergo SHM during ontogeny.¹⁵ This observation supports the idea that similar to mouse human MZ B lymphocytes are generated independent of antigen. However, in this study we observed increased proliferation and SHM in natural effector B lymphocytes from adult blood compared with childhood tonsil, consistent with antigen-induced maturation. Consequently, more insight into the induction of SHM is needed to solve the question whether MZ B lymphocytes and natural effector B lymphocytes in man are generated dependently or independently of antigen.

The T-cell dependent response of B lymphocytes in a germinal center reaction is thought to be more powerful than the T-cell independent response. Our analyses indeed consistently showed that the germinal center response was greater with regard to proliferation and SHM. Interestingly, the replication history of germinal center-derived B cells differed greatly among mice, children, and adults. A plausible explanation is the exposure to antigen. Mice that are 5-12 wk old and kept under specific pathogen-free conditions are exposed to a limited load and spectrum of antigens and likely have less extensive B-cell maturation. Furthermore, the increased proliferation of memory B lymphocytes from adults compared with children correlated with increased frequencies of mutated *IGK* alleles. This could reflect additional maturation resulting from secondary and tertiary immune responses to a specific antigen, or additional activation over time induced by innate stimuli acting on innate antigen receptors, such as Toll-like receptors.⁵⁶

In this study, we introduced the robust KREC assay to quantify the replication history of mouse and human B-lymphocyte subsets *in vivo*. We observed similar trends in both species. In combination with the IgcREHMA assay to determine SHM, this resulted in new and quantitative insights into homeostatic proliferation of naive mature B lymphocytes and the extent of the humoral immune response in healthy individuals. Importantly, the techniques and insights demonstrated in this study provide a firm basis for clinical evaluation of the regeneration of the peripheral B-cell compartment after hematopoietic stem cell transplantation or B cell-directed antibody therapy. Furthermore, these new insights will contribute to the understanding of defects in homeostatic or antigen-induced B-cell proliferation in patients suffering from common variable immunodeficiency or another antibody deficiency.

MATERIALS AND METHODS

Mice, B-cell culture, and B-cell subset isolation

The animal studies were approved by the Institutional Animal Care and Use Committees of the Erasmus University Rotterdam and the University of California, San Diego.

Resting B cells were purified from total splenocytes of young adult C57BL/6 mice (5-12 wk) using the MACS B-cell isolation kit (Miltenyi Biotec), labeled for 10 min at 37°C with 7.5 μ M CFSE, and cultured for 2-3 d in RPMI medium containing 10 % fetal calf serum, 200 U/ml penicillin, 200 μ g/ml streptomycin, 4 mM l-glutamine, and 50 μ M β -mercaptoethanol supplemented with IL-4, anti-IgM, and LPS at 1 ng/ml.

B-cell subsets were purified from spleen and Peyer's patches using a FACSAria cell sorter (BD Biosciences). The following monoclonal antibodies were used: CD21-FITC (7G6), CD23-PE (B3B4), B220-PerCP (RA3-6B2), IgM-biotin (II/41), IgA-biotin (C10-1; all from BD Biosciences), AA4.1-APC, streptavidin PE-cy7, IgM-APC (II/41; all from eBiosciences), and IgD-PE (11-26; Southern Biotechnology Associates, Inc.).

Isolation of (precursor-)B-cell subsets from human bone marrow, peripheral blood, and tonsil

All bone marrow, peripheral blood, and tonsil samples were obtained with informed consent and according to the guidelines of the Medical Ethics Committee of Erasmus MC.

Precursor B cells were obtained from freshly isolated bone marrow samples of three healthy children (age 3-16) as described previously.²⁷

Four B-cell subsets were purified from blood samples of five healthy adults using a FACSDiVa cell sorter (BD Biosciences) after staining of post-Ficoll mononuclear cells that were MACS sorted using CD19 beads (Miltenyi Biotec) with CD27-FITC (LT27; Serotec), IgD-PE, CD19-PE-Cy7 (SJ25C1), and CD5-APC (L17F12; all from BD Biosciences).

Seven tonsillar B-lymphocyte subsets were sorted from tonsils of three children on a FACSDiVa cells sorter after direct staining on freeze-thawed material.¹⁷ Additional monoclonal antibodies used were CD77-FITC (5B5) and CD38-APC (HB7; both from BD Biosciences).

All fractions were obtained with a purity of >95 %.

Generation of control constructs and control cell line for the KREC assay

Mouse kappa-deleting coding and signal joints were PCR amplified from total bone marrow and cloned into the pGEMT-easy vector (Promega). Efficiency was tested on dilution series of the construct. A pGEMT-easy RQ-PCR was performed to correct for input.

A human KREC signal joint was PCR amplified in two parts from bone marrow mononuclear cell DNA to introduce an EcoRI restriction site 60 bp upstream of the Kde RSS heptamer sequence, and subsequently cloned into the retroviral LZRS-IRES-eGFP vector (Figure 3A). The LZRS-KREC construct was transfected into the Phoenix amphotropic packaging cell lines using Fugene-6 (Roche Molecular Biochemicals). Stable hightiter producer clones were selected with puromycin (1 μ g/ml). The U698-M pre-B-cell line was cultured for several days in RPMI 1640 medium containing 10 % FCS and antibiotics before transduction using Retronectin coated Petridishes (Takara) and recombinant retrovirus containing supernatant for 2 d, with daily replenishing of retroviral supernatant. GFP-positive cells were single cell

sorted using a FACSDiVa cell sorter. Individual clones were selected for dim GFP expression, suggesting a single genomic integration.

Southern blot analysis of individual U698-M KREC cell line clones

DNA isolation and Southern blot analysis was performed as previously described.⁵⁷ The configuration of the *IGK* locus was determined using ³²P-labeled probes: the *IGK*-Kde probe is specific for the Kde region,⁵⁸ and the Kde-RSS probe is specific for the region upstream of Kde, which is deleted from the genome after an intronRSS–Kde rearrangement and are present on the KREC construct (Figure 3B).

RQ-PCR and calculation of the replication history of B-cell populations

Primers and probes were designed to specifically amplify the IRS1–RS and intronRSS–Kde rearrangements (coding joint) and the corresponding signal joint using TaqMan-based RQ-PCR from DNA isolated from cell lines and primary material (Figure 1, A and B). The RQ-PCR mixture of 25 μ l contained TaqMan Universal MasterMix (Applied Biosystems), 900 nM of each primer, 100 nM of each FAM-TAMRA-labeled probe, 50 ng of DNA, and 0.4 ng BSA, and was run on the ABIPRISM 7700 sequence detection system (Applied Biosystems).^{59, 60} The primer-probe sets were tested for comparable efficiencies using dilution series of plasmid constructs (for mouse reagents), and DNA was isolated from the U698-M clones DB01, DB11, and DE09, which contain one intronRSS–Kde rearrangement and one KREC construct per genome (for human reagents).

In all experiments, the cycle threshold (C_T) was set at 0.03, and the C_T values of the coding joint and the signal joint were compared for each sample. Because both PCR amplification and cell division are exponential multiplication processes with base 2, the ΔC_T ($C_{T_{\text{intronRSS-Kde}}} - C_{T_{\text{KREC}}}$) from a given cell fraction represents the mean number of cell divisions (Figure 2 A).

SHM analysis using a V κ 3-20-specific restriction enzyme hot-spot mutation assay (Ig κ REHMA) on genomic DNA

To investigate the occurrence of SHM in specific B-cell subsets, we modified the Ig κ REHMA assay developed by Andersen et al.³⁷ for use on genomic DNA (Figure 7A; Appendix 12).

In short, a PCR reaction was performed using a HEX-coupled V κ 3-20 intron forward primer and two FAM-coupled J κ reverse primers recognizing all five J κ gene segments.⁶¹ The PCR products (500 bp) were digested with KpnI and Fnu4HI and run on a Capillary Sequencer ABI 3100 (Applied Biosystems). The Fnu4HI restriction enzyme recognizes two adjacent sites in the unmutated gene product in the SHM hot-spot region of CDR1. Unmutated gene products can therefore be visualized as 244 or 247-bp HEX-coupled fragments. KpnI cuts the gene products in FR2 downstream of the Fnu4HI sites, resulting in a 262-bp HEX-coupled mutated fragment. The unmutated B-cell line CLL-1 was used as a positive control for complete digestion with Fnu4HI. The digests hardly contained undigested gene products of 481 bp, indicating complete digestion by KpnI.

ACKNOWLEDGEMENTS

We thank Dr. C. Murre, Dr. R. W. Hendriks, and Mr. A. van Oudenaren for support with murine studies, Dr. L.J. Hoeve (Erasmus MC-Sophia, Rotterdam, the Netherlands) for providing childhood tonsil material, Mr. E.F.E. de Haas for high-speed cell sorting, Ms. E.J. van Gastel-Mol for Southern blot analysis, Mrs. W.M. Comans-Bitter for assistance in preparing the figures, and Drs. R. Benner and J.D. Laman for critically reading the manuscript.

This work was supported by grants from the foundation “Sophia Kinderziekenhuis Fonds” (grant 349 to M.C. van Zelm, R. de Groot, and J.J.M. van Dongen) and the Dutch Organization for Scientific Research (NWO/ZonMw veni grant 916.56.107 to M. van der Burg).

The authors have no conflicting financial interests.

VII

General Discussion

The research described in this thesis was started with the ultimate goal to identify new genetic defects in patients with a primary antibody deficiency. Since antibodies are produced by plasma cells, which are terminally differentiated B cells, a primary antibody deficiency is likely to be the result of a defect in B-cell development. Therefore, the studies in this thesis aimed to characterize important checkpoints in B-cell development, and when applicable, compare normal with deficient B-cell development.

By studying the immunoglobulin (Ig) gene rearrangement status and the gene expression profile of isolated precursor-B-cell subsets, it was shown that the initiation and selection on complete V to (D)J gene rearrangements were strictly controlled during precursor-B-cell differentiation (**Chapter II**). Furthermore, the *IGH* locus was shown to be structurally organized in multi-loop subcompartments that underwent large-scale compaction when the locus was poised to rearrange (**Chapter III**). In murine pro-B cells, distal V_H gene segments and their promoter regions were repositioned in close proximity of the intronic enhancer region, providing a physical explanation for the mechanisms underlying long-range genomic interactions. Analysis of gross deletion breakpoints involving the *IGHM*, *BTK* and *Artemis* genes in primary immunodeficient patients showed association of transposon-derived repetitive elements, thereby shedding some light on the mechanism underlying these disease-causing mutations (**Chapter IV**). A novel antibody-deficiency syndrome was found to be caused by mutations in the *CD19* gene (**Chapter V**). By comparing of normal and CD19-deficient B cells, it was shown that CD19 plays a crucial role in lowering the signal threshold for B-cell antigen receptor-mediated B-cell activation. The extent of the T-cell independent and the T-cell dependent B-cell proliferative responses were determined using kappa-deleting recombination excision circles (KREC; **Chapter VI**). In addition, homeostatic proliferation of naive B lymphocytes was shown to contribute substantially to naive B-cell homeostasis.

Regulation of Ig gene rearrangements: Ig locus conformation

One of the big unresolved questions regarding B-cell differentiation concerns the highly controlled order in which Ig gene rearrangements are induced. A common machinery is responsible for V(D)J recombination of three Ig and four T-cell receptor (TCR) loci, but how is it possible that in almost every precursor-B cell the same order of rearrangements occurs: *IGH* > *IGK* > *IGL*, and the TCR genes are not rearranged?

The targeting of recombinase activity to a specific locus (or even clusters of gene segments) is controlled at multiple levels, including DNA methylation,¹ chromatin remodeling,² histone acetylation,^{3,4} germ-line transcription,⁵ and transcription elongation.⁶ Epigenetic changes to the DNA or chromatin are induced by enzymes that are specifically recruited to these regions. This local recruitment is likely mediated by transcription factors that recognize specific DNA sequences. Some factors determining the induction of Ig gene rearrangements in precursor-B cells and TCR gene rearrangements in precursor-T cells have been identified. Although two key players, E2A splice variants E12 and E47, are shared by the two lineages, additional factors have been identified to direct induction of either Ig or TCR gene rearrangements. The EBF and Pax-5 transcription factors specifically regulate Ig gene rearrangements in precursor-B cells together with E47 homodimers, whereas HEB-E47 heterodimers are important for TCR gene rearrangements. Obviously these factors are not decisive for all steps, especially considering the fact that a hierarchical order is found during precursor-B-cell differentiation in which the

different Ig loci and even individual alleles are consecutively induced to rearrange.

In **Chapter II** we identified DNA-binding proteins that were specifically upregulated during stages in which *IGH* or *IGK/IGL* gene rearrangements were induced. This specific regulation led us to suggest that these are candidate genes involved in regulation of Ig gene rearrangements. Obviously, functional studies have to be performed to confirm a direct role in induction of Ig gene rearrangements. The Klf4 transcription factor, for example, was found to be specifically upregulated in pre-B-I and small pre-B-II cells. A recent study, however, has shown that Klf4 suppresses proliferation and induces cell death in transformed precursor-B cells.⁷ It is well possible that upregulation in pre-B-I and small pre-B cells does not directly regulate Ig gene rearrangements, but is required to induce arrest in the G1 phase of the cell cycle to allow for the induction of Ig gene rearrangements. Consequently, similar types of overexpression studies, or studies in (conditional) knockout mouse models could help to address this issue. Another possibility is testing the effects of the identified candidate proteins on the induction of Ig gene rearrangements in non-lymphoid cells. Previously, (combinations of) the transcription factors E2A, HEB and EBF have been shown to induce different types of Ig and TCR gene rearrangements in an embryonic kidney cell line.^{8,9} Since the efficiencies of these proteins to induce rearrangements were fairly low, the additional effect of co-expression of the newly identified candidate genes could be measured.

The exact mechanism by which DNA-binding factors mediate Ig gene rearrangement remains mainly unclear. Most importantly, the DNA is made accessible to the RAG proteins and large-scale compaction is induced to allow the joining of two distantly located gene segments. It is commonly believed that promoter and enhancer regions play crucial roles in regulating accessibility of Ig loci to RAG proteins. This has been confirmed in several murine studies. The Pax5 and Stat5a transcription factors bind the promoters of multiple V_H genes segments, and induction of V_H-D_{JH} gene rearrangements was impaired in Pax5^{-/-} and Stat5a^{-/-} pre-B-I cells.^{10, 11} Furthermore, disruption of enhancer regions in the murine *IGH* and *IGK* loci was found to reduce activation of Ig gene rearrangements.¹²⁻¹⁶ More specifically, the E2A binding sites in the intron enhancer of *IGK* are critical for the efficiency of V_κ-J_κ rearrangements.¹⁷ In **Chapter III** we found that the murine *IGH* locus is organized in rosette-like structures that undergo compaction in pre-B-I cells. Since co-localization of distant regions within the *IGH* locus is required for V_H-D_{JH} rearrangement, the structural organization of *IGH* might be crucial for proper efficiency. The specific repositioning in pro-B cells of V_H regions in close proximity of the intronic enhancer region, led us to speculate that factors binding the promoter and enhancer regions play crucial roles in structural organization of *IGH*. Consequently, it would be interesting to see whether disruption of the intron enhancer leads to impaired large-scale compaction of an Ig locus and thereby disturbs the V(D)J recombination process. In absence of Pax5, large-scale contraction of *IGH* and rearrangement of distal V_H gene segments were disturbed.¹⁸ Therefore, it would also be interesting to study the effects of absence of Pax5 and Stat5, or genetic disruption of their target sequences in V_H promoter regions on the structural organization of *IGH*. Using the small 10-kb probes, local effects can be studied, thus addressing for example whether Pax5 is involved in repositioning of the entire V_H region, or only of the distal V_H region.

Alternatively, transcriptional regulators might not act long-range themselves, but are repositioned in close proximity of each other due to reorganization of *IGH* in pro-B cells.

In such a scenario, the reorganization of *IGH* is induced by other factors. Likely candidates are proteins that bind matrix associating regions (MAR) in *IGH*. The gene expression profiles of precursor-B-cell subsets in **Chapter II** showed specific upregulation of transcripts encoding ARID5B, a Bright-like MAR-binding protein, in human pre-B-I cells that initiate V_H-D_H gene rearrangements (data not shown). Thus, this would be an interesting protein to study with respect to the *IGH* locus conformation in developing B cells.

The peripheral B-cell compartment

The precursor-B-cell compartment has been extensively studied and most identified functional processes can now be linked to phenotypically well-defined subsets. Consequently, more attention is now given to the peripheral B-cell compartment with the aim to identify B-cell subsets with unique functional characteristics. The positioning of peripheral B-cell subsets in a scheme is more challenging, because there appears to be no linear differentiation pathway. However, recent studies have provided insight in the identification of several naive and antigen-experienced B-cell subsets (Figure 1).

Naive B-cell homeostasis

Recent bone marrow emigrants are classified as transitional B lymphocytes and can be phenotypically distinguished from naive mature B lymphocytes. In **Chapter VI**, we found that naive mature B lymphocytes undergo homeostatic proliferation, whereas no proliferation was seen in recent bone marrow emigrants, i.e. transitional B lymphocytes. This homeostatic proliferation contributes greatly to the size of the naive mature B-cell compartment. The development of recent bone marrow emigrants into naive mature B lymphocytes is an important checkpoint selection against self-reactive antibodies.¹⁹ It remains unclear whether transitional B lymphocytes undergo selection before they can enter the naive mature B-cell compartment. Transitional B lymphocytes were found to die rapidly in culture, they are unresponsive to BAFF, and although they enter cell cycle upon BCR stimulation with IL-4 and

Figure 1. Important checkpoints in human B-cell differentiation.

Studies described in this thesis have contributed to the identification of 10 important checkpoints, which might be affected in patients with primary antibody deficiency.

CD40 ligation,²⁰ their proliferation, Ig secretion and migration *in vitro* were greatly reduced when compared to naive mature B lymphocytes.²¹ Apparently, transitional B lymphocytes that survive proceed to become naive mature B lymphocytes, but considering the strong reduction of autoreactive clones, survival and/or selection is not dependent on strong BCR signals. On the other hand, the observed selection of transitional B lymphocytes into the naive mature B-cell compartment might be the result of selective proliferation of non-autoreactive cells. This would explain the reduction in autoreactivity and the observed homeostatic proliferation of naive mature B lymphocytes. The question then remains how specifically non-autoreactive transitional B lymphocytes are induced to proliferate.

Homeostatic proliferation of naive mature B lymphocytes has been observed before in mouse models in response to B-cell deficit and was independent from T-cell help.^{22,23} The c-rel and p50 components of NF- κ B were dispensable for this proliferation.²³ C-rel is critical for antigen and mitogen stimulation and p50 for the survival of peripheral B cells. Consequently, homeostatic proliferation occurs most likely independent from antigen or other means of BCR stimulation.

Homeostatic proliferation was found to critically depend on Btk, which does not only signal downstream of the BCR, but also other surface receptors mediating B-cell growth and proliferation (IL-5R, IL-10R, the Toll-like receptor RP-105) and migration (CD38). Consequently, there might be a role for cytokine stimulation of naive mature B lymphocytes to mediate homeostatic proliferation. In addition, the BAFF – BAFF-R interaction could be involved in induction of homeostatic proliferation. BAFF-R signals are crucial for B-cell survival, but initiate signaling and transcriptional programs that increase the metabolic activity.^{24, 25} This metabolic fitness has been shown to result in a more rapid and robust response to BCR or TLR stimulation *in vitro*.²⁵ It is therefore likely that a combination of cytokine and BAFF-induced signaling initiates homeostatic proliferation.

During development, a B-cell undergoes consecutive stages of differentiation and proliferation. These processes are highly controlled and often E-proteins and their inhibitors (Id proteins) are involved. The E-protein dimers initiate differentiation, whereas Id proteins inhibit the E-protein function by forming E-Id heterodimers. The Id3 protein is expressed throughout B-cell differentiation except in plasma cells,²⁶ and B lymphocytes of Id3^{-/-} mice show impaired proliferation upon stimulation with anti-IgM, LPS, anti-CD38, anti-CD40.²⁷ Considering the role of Id3 in peripheral B-cell proliferation, it can well be anticipated that this is one of the genes involved in the induction of homeostatic proliferation.

Theoretically, the absolute number of naive B lymphocytes is regulated by four processes: (a) output from bone marrow; (b) survival; (c) loss of naive B lymphocytes via further maturation after antigen encounter; and (d) antigen-independent homeostatic proliferation. Understanding the contribution of these four processes to naive B-lymphocyte homeostasis is of great importance for diagnosis and clinical evaluation of several patient categories. It would be interesting to determine the contribution of proliferation to regeneration of the B-cell compartment following anti-B-cell therapy (e.g. rituximab treatment) or stem cell transplantation in relation to the clinical status of the patient. Homeostatic proliferation can support the expansion of peripheral B-cell numbers, but the patient needs a B-cell compartment with a broad repertoire. Therefore, the balance between the output of B cells from bone marrow and peripheral expansion of these cells has to be tightly controlled.

Furthermore, the KREC assay can be a powerful tool to monitor the peripheral B-cell compartment in patients with a lymphoproliferative disorder. For instance, patients with XLP (X-linked lymphoproliferative disease) that carry a genetic defect in *SH2D1A* have an expansion of transitional B lymphocytes.^{21, 28-30} The over-abundance of transitional B lymphocytes may contribute to the humoral deficiency that accompanies the disease. The question remains, however, whether this expansions results from extra output from bone marrow, a reduced loss of these cells, or increased proliferation.

The B-cell antigen response

The response of B lymphocytes upon antigen recognition was studied in **Chapter V** and **Chapter VI**. In **Chapter V**, we described four patients with a homozygous disruption in the *CD19* gene. *In vitro* Ca^{2+} flux and proliferation studies revealed that CD19-deficient B cells were not optimally activated upon BCR stimulation. As a result, the number of CD27⁺IgM⁺IgD⁺ natural effector B cells and CD27⁺IgM⁻IgD⁻ class-switched memory B cells, the Ig response to rabies vaccination and the total serum Ig levels were drastically reduced in CD19-deficient patients. This is most likely caused by a decreased number of naive B lymphocytes that are activated by antigen and/or centrocytes that are positively selected for by optimal antigen-binding capacities. These data confirm previous observations that CD19 acts in a complex with CD21, CD81 and CD225 to lower the threshold for signal transduction.^{31, 32} The CD19 deficiency is the first genetic defect identified in man that specifically leads to a decreased response of B lymphocytes to antigen.

Recently, a CD21⁻ mature B-cell subset identified in peripheral blood of rheumatoid arthritis patients was described to be anergic (E. Meffre, B cells in health and disease, Keystone symposia series, Banff, Alberta, Canada, 2007). Interestingly, mature B cells of CD19-deficient patients have decreased CD21 expression levels. Human B cells apparently become anergic when the CD19-complex, either by absence of CD19 or CD21, is disrupted.

The extent of B-cell proliferation upon antigen recognition was studied in **Chapter VI**. Two types of antigen responses can be identified. Splenic marginal zone B lymphocytes mainly undergo a fast, T-cell independent response (reviewed in ref. 33). Human marginal zone B lymphocytes carry a memory phenotype (CD27⁺) and mutated Ig genes.^{34, 35} Their counterparts, natural effector B lymphocytes, are found in lymph nodes, tonsils, Peyer's patches and blood.³⁶⁻³⁹ Although these cells show the characteristics of antigen-experienced cells, it is currently under debate, whether these cells develop independently from antigen during ontogeny or in response to antigen.³⁹⁻⁴¹ Our data show increased proliferation and SHM in natural effector B lymphocytes from adult blood compared with childhood tonsil, consistent with antigen-induced maturation. On the other hand, we found that in young mice, kept under specific pathogen-free conditions, marginal zone B lymphocytes showed similar extensive proliferation as human natural effector B lymphocytes. Further analysis of SHM and proliferation in this subset could help to resolve this issue. Sequencing of the V_H-C_μ transcripts should reveal whether the pattern of SHM shows a molecular sign of a response to antigenic stimulation.⁴² Furthermore, the KREC assay can be used to analyze whether marginal zone B lymphocytes undergo proliferation in animals that are kept completely in absence of pathogens.

B lymphocytes undergoing a T-cell dependent antigen response in the germinal center showed most proliferation (**Chapter VI**). Centroblasts, centrocytes, and germinal center-

derived class-switched memory B cells and plasma cells showed a replication history of 8 cycles in childhood tonsil. Interestingly, class-switched memory B cells in adult peripheral blood showed a clearly higher replication history of 11 cell cycles. Since this increase correlated with an increase in SHM, this is likely to be the result of additional maturation resulting from secondary and tertiary immune responses. A more detailed study on the replication history of B-cell subsets from healthy controls ranging in age from birth to 80 years would provide more insight into the build up of memory by additional proliferation in consecutive immune responses.

It is a long-standing concept that the adaptive immune system forms memory during a primary response to antigen. These cells will show a faster and more powerful response upon second contact with the same antigen, thus preventing disease and resulting in immunity. Although our results are in line with this concept and suggest additional proliferation, we were unable to demonstrate (a) the magnitude of the memory B-cell response and (b) the contribution of naive and memory B cells upon a second encounter with the same antigen (Figure 2). This multifactorial problem can probably not be solved with human studies. The use of mouse models, however, should facilitate this, because mice that are kept under specific pathogen-free conditions have only small germinal centers and limited numbers of class-switched memory B cells. Consequently, the immune response upon immunization with a specific hapten can be studied in a relatively ‘clean’ system. Furthermore, when using a conjugate of (4-hydroxy-3-nitrophenyl)acetyl (NP) with, for instance, keyhole limpet hemocyanin (KLH), a substantial population of antigen-specific B cells are formed.^{43, 44} These cells can be identified flowcytometrically by their ability to bind 4-hydroxy-3-iodo-5-nitrophenylacetate (NIP) conjugated to PE. Thus, the replication history of these cells, in addition to other immunological parameters, can be determined after primary and secondary immunizations. The secondary response will involve both naive and memory B cells formed during the primary response. Additional experiments will have to be performed to determine the response of memory B cells. An option is to treat these mice with anti-BAFF prior to secondary immunization. All mature B-cell subsets, except for memory B cells, depend on BAFF and will go in apoptosis upon treatment with anti-BAFF (J.E. Crowley, B cells in health

Figure 2. Model of a germinal center reaction during a secondary immune response.

Upon secondary encounter with an antigen, both naive and memory B cells can be activated and recruited in a germinal center reaction. The contribution and the extent of the primary and memory response upon secondary antigen encounter are currently unknown. Application of the KREC assay in murine immunization studies could provide more insight into the issue.

and disease, Keystone symposia series, Banff, Alberta, Canada, 2007). Thus, upon anti-BAFF treatment only memory B cells will be present for participation in the secondary response.

New approaches to identify B-cell defects in patients suffering from an antibody deficiency

In >90 % of patients that suffer from an antibody deficiency, no genetic defect has been found to underlie the disease. The majority of these patients are diagnosed as having common variable immunodeficiency (CVID) and although the presentation of the disease and the susceptibility to pathogens varies considerably, they are currently treated and studied as a single disease entity. Recently, we (**Chapter V**) and others (refs. 45-47) have identified new genetic defects in patients that were previously diagnosed as having CVID. These defects resulted in a block in peripheral B-cell development and thus showed that these molecules play crucial roles in important checkpoints in B-cell development. Previously identified genes disrupted in antibody deficiencies were found to be crucial for either pre-BCR signaling or Ig class switching in the germinal center.⁴⁸⁻⁵⁷ We anticipate that in CVID patients, B-cell differentiation is blocked in these or other critical checkpoints.

Based on human studies in healthy controls, primary antibody deficient patients, and mouse models, we identified 10 critical checkpoints in B-cell development (step A-I in Figure 1). First, multipotent progenitor cells in bone marrow have to develop into pro-B cells. Multiple factors are required to induce specification and subsequently commitment to the B-cell lineage. The importance of this first checkpoint (step A) was demonstrated in multiple mouse models, such as the *E2A^{-/-}* and the *EBF^{-/-}* mice that show a complete absence of all precursor-B cells in bone marrow.^{58, 59} Signaling via the pre-B cell receptor (pre-BCR) at the pre-B-II large stage is the second important checkpoint (step B) and precedes a proliferation phase.⁶⁰ A proportion of the immature B cells is autoreactive and is either deleted by apoptosis, becomes anergic, or generates an altered B-cell receptor via receptor editing (step C).⁶¹ Immature B cells that are not autoreactive leave the BM and migrate to the periphery as transitional B lymphocytes and develop into naive mature B lymphocytes if they are able to survive and proliferate (step D). These naive mature B lymphocytes can be activated by antigen (step E) and differentiate into marginal zone or memory B cells depending on the type of antigen. Marginal zone B cells and their counterparts in peripheral blood and other lymphoid tissues clearly differ from class-switched memory B lymphocytes in their replication history and SHM load (**Chapter VI**). Furthermore, they show a fast and mainly T-cell independent response to antigen (step F; reviewed in ref. 33) A cognate B-T cell interaction is required for activation with a T-cell dependent (TD) antigen (step G) and the initiation of the affinity maturation process (step H), which aims for the generation of B cells with the highest affinity for the antigen in the germinal center response. The affinity maturation process is based on the generation of somatic hypermutations (SHM) and subsequent selection and class switch recombination to IgA, IgG or IgE. Finally, maturation into memory B cells (step I) or antibody-secreting plasma cells takes place (step J).⁶² The techniques we used and the insights we obtained from the studies described in this thesis can be used to investigate possible B-cell defects in patients suffering from an antibody deficiency.

Biology of germline mutations: small and gross deletions

In **Chapter IV** we studied gross deletions in three primary immunodeficiency (PID) genes with the aim to identify underlying mechanisms involved in their induction. In contrast to micro-lesions, the molecular mechanisms mediating gross lesions are still poorly understood. Random mispairing of 2-8 bp repeats in the replication fork is a likely origin of micro-deletions and -insertions, because the involved repeats are in close proximity to each other. In contrast, gross lesions involve DNA sequences that can be hundreds of kb apart. Consequently, additional mechanisms have to be involved to bring these sequences close to each other.

In **Chapter III** we showed using distance measurements between multiple regions in the murine *IGH* locus that the locus has a very compact and organized structure in which subdomains can be identified. These data showed that genomically distant regions can be located in spatial proximity of each other in the nucleus. In **Chapter IV** we found that a high local content of transposon-derived elements was associated with increased incidence of gross deletions. There are several indications that high density of transposon-derived elements in a genomic region can alter the structural organization of that region. First, transposons greatly influence the GC/AT ratio of the genomic region in which they integrate. For instance, *Alu* repeats have a high GC content (~63 %). Second, transposon-derived elements alter the epigenetic regulatory structures. Transposon integration can trigger CpG methylation and histone deacetylation of the involved genomic region, thereby resulting in localization in heterochromatin.^{63,64} These combined observations indicate that transposon-derived elements are possible mediators of gross deletions by the co-localizing genomically distant regions.

Genetic diagnosis of primary antibody deficiencies: considerations and new approaches

In our diagnostic setting, we aim for the identification of a genetic defect with molecular methods in patients suspected to suffer from a primary immunodeficiency. A molecular diagnosis has several advantages over the clinical or immunological diagnosis.⁶⁵ First, the presence or absence of a mutation can be determined unambiguously. Second, the specific mutation may provide prognostic information. Third, molecular diagnostic testing allows the screening of family members for carriers or other affected individuals prior to the appearance of clinical symptoms. Fourth, molecular diagnosis is required for corrective treatment with gene therapy. Although gene therapy to treat primary immunodeficiencies has not been developed beyond clinical trials and has faced some setbacks,⁶⁶⁻⁷⁰ it is still the most promising corrective treatment.

Besides the clear advantages, molecular testing also has several clear limitations. The techniques are relatively costly and laborious. Therefore, a candidate gene has to be selected before starting molecular analysis. Since the human genome contains >30,000 genes, the gene has to be carefully selected based on the clinical and immunological findings. Furthermore, it is not always clear whether the identified mutation is disease-causing. Single point mutations that alter one amino acid could be harmless polymorphisms. In such situations, the clinical and immunological findings or additional protein analysis might be required to support the genetic diagnosis. Finally, gross lesions can be very difficult to detect. The presence of a deletion is hard to confirm with a positive result (**Chapter IV**), but the detection of inversions is even more difficult. Because the genetic material is still present in the genome, PCR amplification and

sequencing will not result in abnormal findings. However, these lesions result in loss of normal transcripts. Therefore, these limitations should be taken into account and additional assays should be performed to reduce false positive or false negative results in molecular diagnosis.

Molecular diagnosis in CVID patients proves to be extremely difficult; until now in <10 % of patients a genetic defect has been identified. The difficulties result from (a) the heterogeneity of the disease and (b) the fact that in many cases not a monogenetic defect, but a complex genetic trait underlies the disease. As stated before, clinical and immunological characterization of the patient will help to guide molecular diagnostics. However, this could still generate multiple candidate genes. Consequently, a different approach using new techniques is needed for large-scale screening to identify a molecular basis of the disease in individual CVID patients.

In large families with multiple patients, linkage analysis can be performed to identify genomic regions with candidate genes. The standard method involves a whole-genome scan using 300-400 microsatellite markers spaced at ~10 Mb intervals.^{71, 72} Although several monogenetic disorders were mapped with this approach, it is not optimal for the identification of disease susceptibility genes in complex traits.⁷³ More recently, DNA microarrays have been developed that detect >500,000 SNPs (Affymetrix). With a mean distance between markers of <8 kb, these SNP arrays can be much more powerful for linkage studies.⁷⁴ The exact strength of SNP chips in small families has to be determined, but in combination with the clinical and immunological characterization of the patient, this will further restrict the number of candidate genes that might be affected.

In addition to SNP detection, arrays have been developed to enable analysis of up to 300 kb of genomic sequence. These arrays enable sequence analysis of multiple candidate genes and can greatly facilitate molecular diagnosis. However, considering the possibility of technical errors due to the large-scale approach, identified mutations will have to be confirmed by standard sequencing methods. Furthermore, this approach mainly aims for the identification of small lesions and false negative results can be obtained when a gross lesion underlies the disease. Nevertheless, the use of these types of DNA microarrays will greatly support the identification of genetic defects in patients suffering from an antibody deficiency.

New insights in human B-cell differentiation resulting from the identification of novel monogenetic defects in patients with a primary antibody deficiency

As discussed above, our studies on normal and deficient B-cell differentiation can support future studies on and diagnostic testing of primary antibody deficiencies. The identification of an immunological defect and especially a molecular defect underlying the disease is a relevant ultimate aim of this type of research. However, we should realize that there is more: there is a lot to be learned from well-defined groups of patients. Especially when a monogenetic defect appears to cause the disease, the antibody-deficiency syndrome of a patient can be used as a model. The affected gene apparently has a critical role in maintaining immunity, and its absence results in a block in B-cell differentiation or in the antibody response. Therefore, studies on antibody-deficient patients can support our understanding of important checkpoints in normal B-cell differentiation as well as studies on normal B-cell differentiation do this to define the immunological defects in patients with an antibody deficiency.

Appendix 4. Full width at half the maximum (FWHM) values of the point spread function for the indicated colors.

Color	dimension		
	X (nm)	Y (nm)	Z (nm)
Green (Alexa-488)	543.40	489.06	1800
Red (Alexa-594)	380.38	380.38	1400
Dark Red (Alexa-647)	434.72	434.72	1700

Appendix 5. Chromatic shifts.

	red vs. green (in nm)			red vs. dark red (in nm)			dark red vs. green (in nm)		
	X	Y	Z	X	Y	Z	X	Y	Z
average	31.7	-14.4	-133.0	-21.8	-11.6	26.1	53.5	-2.8	-159.1
standard deviation	16.5	17.2	35.3	22.9	25.0	36.6	30.2	31.5	24.9

Appendix 6. Resolution equivalents before and after application of chromatic corrections.

Color combination	average \pm SD \pm SE (in nm)	average \pm SD \pm SE (in nm)
	before correction	after correction
Red (Alexa-594) - Green (Alexa-488)	139.7 \pm 34.6 \pm 2.3	34.9 \pm 24.3 \pm 1.6
Red (Alexa-594) - Dark Red (Alexa-647)	56.3 \pm 24.6 \pm 1.6	44.6 \pm 22.1 \pm 1.5
Dark Red (Alexa-647) - Green (Alexa-488)	173.2 \pm 26.2 \pm 1.7	46.8 \pm 17.8 \pm 1.2

SD: standard deviation

SE: standard error

TLR	Toll-like receptor
TNF	tumor necrosis factor
TREC	T-cell receptor excision circle
UCB	umbilical cord blood
UNG	uracil-N-glycosylase
V	variable
XLP	X-linked lymphoproliferative disease

SUMMARY

B lymphocytes are generated throughout life from hematopoietic stem cells in bone marrow, and contribute to the immune system by the production of antigen-specific antibodies (immunoglobulins; Ig). Two distinct phase of B-cell development can be distinguished: 1) antigen-independent precursor-B-cell differentiation in bone marrow, and 2) antigen-dependent B-cell maturation in peripheral lymphoid organs. The aim of precursor-B-cell differentiation is to generate a functional Ig receptor by V(D)J recombination of the genes encoding the Ig heavy (IgH) and Ig light (Ig κ or Ig λ) chains. When a precursor-B-cell succeeds in creating a functional Ig receptor, it will migrate to the periphery and become part of the naive B-cell pool. Because every precursor-B-cell creates a unique Ig receptor, the peripheral B-cell pool bears a diverse repertoire of specific receptors for antigen.

Naive B lymphocytes are short-lived cells and because new cells are continuously generated, there is a high turnover. However, once a naive mature B-lymphocyte recognizes antigen with its specific Ig receptor, it will undergo clonal proliferation and differentiation, thereby generating a large number of plasma cells that produce and secrete antigen-specific Igs. During this response, the B-cell initiates additional molecular mechanisms to adapt and optimize the antigen-binding affinity and the effector function of its Ig molecule.

Generation of a large repertoire of B lymphocytes and the response of one of these B lymphocytes to antigen is a multi-step process for which multiple proteins are required. The lack of one of these proteins leads to a problem with the humoral immunity of the individual, which is seen in patients with primary antibody deficiency diseases. These children or young adults carry rare inherited disorders and are subject to multiple, recurrent (mainly) bacterial infections. Several genetic defects have been identified in patients with a primary antibody deficiency. In many patients, however, the B-cell defect is not well understood. The studies in this thesis address several aspects of B-cell development and defects that lead to primary antibody deficiency diseases.

Most primary antibody-deficient patients with extremely low serum Ig levels carry a defect in precursor-B-cell differentiation in bone marrow. Several gene defects (*BTK*, *IGHM*, *BLNK*, *CD79A*, *L14.1*) have been identified that result in a block in precursor-B-cell differentiation, but the nature of the defect in (5 - 10 %) of the patients remains unknown. In **Chapter II**, we studied normal precursor-B-cell differentiation in childhood bone marrow. We purified precursor-B-cell subsets with membrane markers only, thus enabling the extraction of both DNA for analysis of the Ig gene rearrangements using real-time quantitative (RQ-)PCR and GeneScan assays, and RNA for genome-wide gene expression profiling using Affymetrix GeneChip arrays. Based on the Ig gene rearrangement patterns we divided human precursor-B-cell differentiation into five functional stages. Pro-B cells already massively initiate D_H-J_H rearrangements, which are completed with V_H-D_H rearrangements in pre-B-I cells. Large cycling pre-B-II cells are selected for in-frame *IGH* gene rearrangements. The first *IGK*/*IGL* gene rearrangements were initiated in pre-B-I cells, but their frequency increased strongly in small pre-B-II cells, and in-frame selection was found in immature B cells. Transcripts of the *RAG1* and *RAG2* genes, and earlier defined transcription factors, such as *E2A*, *EBF*, *E2-2*, *PAX5* and *IRF4*, were specifically up-regulated at stages undergoing Ig gene rearrangements. Careful analysis of genome-wide expression profiles of these five subsets enabled us to

identify 16 novel candidate genes for initiation and regulation of *IGH* and *IGK/IGL* gene rearrangements, thereby providing insight in the mechanism of precursor-B-cell differentiation. Furthermore, this detailed analysis represents an excellent template for studies on B-cell differentiation blocks in patients with a primary antibody deficiency.

The Ig gene rearrangements status can be used to determine the differentiation stage of a precursor-B cell. The induction of Ig gene rearrangements appears to be tightly controlled, but the molecular mechanisms underlying the hierarchical order found in **Chapter II** are largely unknown. In **Chapter III**, we studied how a large region spanning three megabases allows efficient joining of V and D region gene segments. Using a 3D fluorescence *in situ* hybridization approach we labeled eleven regions of the *IGH* locus with small DNA probes in uncommitted E2A-deficient pre-pro-B and committed RAG-deficient pro-B cells. Subsequently, we measured the end-to-end physical distances separating these markers to determine the structural organization of the murine *IGH* locus. Our observations show that in pre-pro-B and pro-B cells, the distance distribution within the *IGH* locus is most consistent with a 30 nm fiber that is organized into two rosettes that contain multiple loops (two ‘flowers’). The data also indicate that in pre-pro-B cells V_H regions positioned in proximal and distal genomic regions are localized at similar spatial distances from the D_H and J_H elements. Furthermore, we show that it is the geometry of the *IGH* locus in interphase pro-B cell nuclei that allows V_H and D_HJ_H gene segments, as well as V_H promoters and the intron enhancer, to find each other over large genomic distances with relatively high frequency. This is the first study to demonstrate the structural organization of a genetic locus.

The majority of gene disruptions underlying human inherited diseases are micro-lesions smaller than 20 bp. Whereas this is true for *BTK* gene disruptions, about half of the mutated *IGHM* and *Artemis* alleles are disrupted by gross deletions. A mechanism for this striking difference has never been reported. In **Chapter IV**, we studied the gross deletion breakpoints involving the *IGHM*, *BTK* and *Artemis*. The *IGH* locus is complex and in developing B cells, large genomic regions are deleted during V(D)J recombination and Ig class switch recombination. We did not find involvement of RSS or Ig switch regions in the breakpoints of five unique *IGHM* gross deletions. In contrast, most gross deletion breakpoints were located in or near transposon-derived elements (TE). Similar observations were made for gross deletions in *BTK* and *Artemis*. However, whereas the *IGH* gross deletion breakpoints showed involvement of long interspersed elements (LINE) and LTR retrotransposons (ERV), *BTK* and *Artemis* gross deletion breakpoints were mainly located in or near short interspersed elements (SINE). This difference could be explained by the fact that LINE and ERV elements are specifically overrepresented in the *IGH* locus as compared to the average of the human genome, and SINEs are overrepresented in the *BTK* and *Artemis* genes. The high frequency of gross deletions in *IGH* and *Artemis* was associated with a high total TE content. We performed similar analyses on literature data of extensively studied genes in human genetic disorders. The observations made in *IGHM*, *BTK* and *Artemis* were confirmed in a total set of 20 genes, thereby supporting a model in which the TE content of a genomic region influences the gross deletion incidence. Thus our data shed some light on the mechanism underlying gene disruption by gross deletion.

In **Chapter V**, we described four antibody-deficient patients from two unrelated families with strongly reduced serum Igs. These patients had normal numbers of B cells in their

peripheral blood, but these cells lacked membrane expression of CD19. Sequence analysis revealed homozygous mutations in the *CD19* gene that resulted in premature stop codons. The CD19 protein forms a complex with CD21, CD81, and CD225 on the membrane of mature B cells. Together with the B-cell antigen receptor, this complex signals the B cell to decrease its threshold for activation by the antigen. Expression of CD21 was reduced, whereas the other two CD19-complex members CD81 and CD225 were found to be normally expressed on patients' B cells. All four patients showed reduced numbers of CD27⁺ memory B cells. Small-to-moderate size germinal centers were found in secondary lymphoid organs, and Ig class switched *IGH* transcripts contained somatic mutations. However, stimulation of B cells with anti-IgM resulted in impaired Ca²⁺ flux and proliferation. Furthermore, the antibody responses upon rabies vaccination were quantitatively and qualitatively impaired. This study shows that the disruption of CD19 signaling results in a primary antibody deficiency, mainly characterized by a poor antigen-specific response. On the basis of the crucial role of CD19 in signaling by the B-cell receptor on antigen recognition, it is likely that defects in other members of the CD19-complex (CD21, CD81, and CD225) also lead to antibody deficiency in humans.

The contribution of proliferation to B-lymphocyte homeostasis and antigen responses is largely unknown. In **Chapter VI**, we quantified the replication history of mouse and human B-lymphocyte subsets by calculating the ratio between genomic coding joints and signal joints on kappa-deleting recombination excision circles (KREC) of the *IGK*-deleting rearrangement. We demonstrate that naive mature B lymphocytes, but not transitional B lymphocytes, undergo *in vivo* homeostatic proliferation in absence of somatic mutations in the periphery. T-cell dependent B-cell proliferation was substantially higher and showed higher frequencies of somatic hypermutation than T-cell independent responses, fitting with the robustness and high affinity of T-cell dependent antibody responses. More extensive proliferation and somatic hypermutation in antigen-experienced B lymphocytes from human adults compared to children indicated consecutive responses upon additional antigen exposures. Our combined observations unravel the contribution of proliferation to both B-lymphocyte homeostasis and antigen-induced B-cell expansion. We propose an important role for both processes in humoral immunity. These new insights will support the understanding and the identification of defects in homeostatic or antigen-induced B-cell proliferation in patients with common variable immunodeficiency or another antibody deficiency.

The studies described in this thesis support the understanding of important processes in B-cell development and the molecular basis of primary antibody deficiencies. Still, in many patients suffering from an antibody deficiency, the B-cell deficiency and the possible molecular basis are not yet understood. Extensive characterization of the B-cell compartment in these patients should facilitate the identification of B-cell differentiation blocks in these patients. Furthermore, new approaches in DNA chip technology can support molecular diagnostics by linkage analysis in large families or the direct identification of gene disruptions in likely candidate genes.

SAMENVATTING

B cellen zijn witte bloedcellen, die een belangrijke rol spelen in het immuunsysteem, omdat ze antistoffen produceren. Antistoffen kunnen een ziekteverwekker of ander lichaamsvreemd bestandsdeel (antigeen) herkennen en door er stevig aan te binden speelt het een belangrijke rol in het onschadelijk maken van ziekteverwekkers. B cellen worden gedurende het hele leven aangemaakt in het beenmerg, waar ze ontwikkelen uit bloedstamcellen. Tijdens de voorloper-B-cel ontwikkeling in het beenmerg creëert elke voorloper-B cel een uniek antistofmolecuul dat als receptor op het celoppervlak wordt gezet om antigenen te herkennen. Dit antistofmolecuul, ook wel immuunglobuline (Ig) genoemd, bestaat uit twee Ig zware eiwitketens (IgH) en twee Ig lichte eiwitketens (Igκ of Igλ).

Een antistof is specifiek voor één antigeen, en aangezien er enorm veel verschillende antigenen zijn, moeten er dus minstens zo veel verschillende antistoffen worden aangemaakt om het lichaam te beschermen. Om dit te kunnen doen worden in elke voorloper-B cel de stukken DNA die coderen voor de IgH, Igκ en Igλ eiwitketens herschikt. Het *IGH* gen bevat 66 variable (V), 27 diversity (D) en 6 joining (J) gensegmenten. Een speciaal herschikkingsmechanisme zorgt ervoor dat in een voorloper-B cel een V, een D en een J gensegment aan elkaar worden gekoppeld. Dit zogenaemde V(D)J recombinatie proces vindt ook plaats in de *IGK* en *IGL* genen, die uitsluitend V en J segmenten bevatten. De V(D)J koppelingen zijn niet precies, doordat DNA bouwstenen (nucleotiden) op de koppelplaats kunnen worden verwijderd en willekeurig worden ingevoerd; dit zorgt voor extra diversiteit. Er zijn drie factoren die bijdragen aan de diversiteit van het antistofrepertoire: de combinatie van V(D)J gensegmenten, de V(D)J koppelplaats, en de combinatie van Ig zware en Ig lichte ketens. Gezamenlijk kan dit een repertoire van meer dan duizend miljard ($>10^{12}$) verschillende antistoffen opleveren.

Elke voorloper-B cel maakt dus een eigen unieke Ig molecuul en brengt hiervan duizenden exemplaren op het celoppervlak tot expressie. Vervolgens verlaat deze B cel het beenmerg via de bloedbaan en migreert tussen de verschillende lymfoïde organen, zoals de milt en lymfklieren, op zoek naar antigenen. Wanneer een B cel antigeen herkent, zal deze worden geactiveerd en meerdere celdelingen doormaken, zodat er veel B cellen ontstaan met dezelfde Ig moleculen. Deze dochtercellen brengen willekeurige veranderingen aan in het DNA van hun Ig zware en Ig lichte keten. Deze veranderingen kunnen de bindingscapaciteit aan antigenen beïnvloeden. Doordat alle dochtercellen geselecteerd worden op goede binding met antigenen, vindt er selectie plaats van B cellen met Ig moleculen die het sterkst aan het antigeen binden. De geselecteerde dochtercellen rijpen vervolgens uit tot plasmacellen, die antistoffen produceren, of tot geheugencellen, die zeer snel in actie kunnen komen zodra hetzelfde antigeen nog een keer het lichaam binnenkomt.

Patiënten met een primaire antistofdeficiëntie kunnen geen goede antistoffen maken. Dit zijn vaak jonge kinderen, die daardoor meerdere zware bacteriële infecties per jaar doormaken. De enige behandeling voor deze patiënten is om elke drie weken antistoffen van gezonde donoren te krijgen. Bovendien hebben ze regelmatig antibiotica kuren nodig om infecties snel en tijdig te bestrijden. Deze patiënten hebben veelal een aangeboren afwijking, die wordt veroorzaakt door mutatie van een gen dat belangrijk is voor een goede B-celontwikkeling. In dit proefschrift is onderzoek gedaan naar de B-celontwikkeling en de

moleculaire processen nodig zijn om goede antistoffen aan te maken, maar die mogelijk defect kunnen zijn bij patiënten met een antistofdeficiëntie.

In **Hoofdstuk II** hebben we de voorloper-B-celontwikkeling bestudeerd in het beenmerg van gezonde kinderen. Wij konden deze ontwikkeling opsplitsen in 5 verschillende stadia, en cellen van elk stadium isoleren. Pro-B cellen (1) ondergingen D–J genherschikkingen voor de Ig zware keten, terwijl V–DJ genherschikkingen pas werden gevonden in pre-B-I cellen (2). Vervolgens vond er in large pre-B-II cellen (3) selectie plaats op functionele Ig zware ketens, waarna in small pre-B-II cellen (4) V–J genherschikkingen plaatsvonden voor de Ig lichte ketens. Tot slot werden immature B cellen (5) geselecteerd voor functionele Ig lichte ketens. Vervolgens hebben we de voorloper-B cellen van deze 5 stadia onderzocht om vast te stellen met DNA microchips welke genen tot expressie kwamen. Dit verschaftte ons meer inzicht in de processen die plaatsvonden in deze 5 stadia van de normale voorloper-B-celontwikkeling. Deze inzichten kunnen we in de toekomst gebruiken voor verder onderzoek bij antistofdeficiënte patiënten met een probleem in de voorloper-B-celontwikkeling in het beenmerg. Het zou interessant zijn om de geblokkeerde B-celpopulatie van deze patiënten te vergelijken met de normale tegenpool van deze studie.

In **Hoofdstuk III** hebben we de structuur van het *IGH* gen bestudeerd in muizenmodellen. Het *IGH* gen is bijzonder groot en tijdens voorloper-B-celontwikkeling vindt er V(D)J recombinatie plaats tussen gensegmenten die ver uit elkaar liggen. Het is nog onduidelijk hoe deze gensegmenten bij elkaar worden gebracht. Om dit te bestuderen hebben we stamcelachtige pre-pro-B cellen uit E2A-deficiënte muizen en pro-B cellen uit RAG-deficiënte muizen geïsoleerd. Beide muizensoorten hebben een blokkade in de voorloper-B-celdifferentiatie en zijn niet in staat om V(D)J recombinatie te ondergaan, zodat het recombinatieproces niet de structuur van het *IGH* gen kan beïnvloeden. In deze cellen hebben we met fluorescerende DNA markers het *IGH* gen aangekleurd en in 3D opnames de onderlinge afstanden bepaald. In totaal hebben we de afstanden tussen 11 markers in het IgH gen en een marker net buiten het *IGH* gen bepaald. Op grond van deze data hebben we een model kunnen maken van de structuur van het *IGH* gen. Het *IGH* gen bestaat uit 1 of 2 subcompartimenten die het best kunnen worden beschreven als bundels van lussen, gescheiden door een tussenliggende verbinding. Hieruit bleek dat in pro-B cellen, de V_H gensegmenten dicht bij de D_H en J_H gensegmenten liggen dan in de onrijpere pre-pro-B cellen. Ook de V_H gensegmenten die theoretisch verder weg lagen, bleken in 3D ruimte net zo dichtbij als de andere V_H gensegmenten. Bovendien bleek de structuur van het *IGH* locus zodanig dat specifiek in pro-B cellen de V_H gensegmenten de D_H en J_H gensegmenten elkaar over grote genomische afstanden vinden en V(D)J recombinatie mogelijk is. Dit onderzoek toont voor het eerst de structuur van een gen aan en hoe interactie tussen ver uiteen gelegen elementen mogelijk wordt gemaakt. In vervolgstudies zal worden onderzocht welke DNA elementen een belangrijke rol spelen in de regulatie van de structurele organisatie van een gen.

Het grootste deel (>90 %) van de mutaties in genen die leiden tot een erfelijke ziekte zijn puntmutaties, kleine deleties, of kleine inserties (<20 nucleotiden). Grote veranderingen komen minder frequent voor en grote deleties vormen hierin de grootste groep (~6 % van de mutaties). In **Hoofdstuk IV** hebben we grote deleties van *IGHM*, *BTK* en *Artemis* bestudeerd om meer te weten te komen over de onderliggende mechanismen. Grote deleties komen in de *IGHM* en *Artemis* genen komen frequent voor vergeleken met grote deleties in

het *BTK* gen (~50 % t.o.v. 6 % van de mutaties). Daarnaast bevat het *IGH* locus vele DNA motieven die bij herschikkingsprocessen tijdens B-celontwikkeling grote deleties mediëren. Met PCR technieken hebben we de breukpunten van 5 verschillende *IGHM* deleties onderzocht. Na uitgebreide analyse vonden we geen aanwijzing voor DNA motieven die betrokken konden zijn bij het optreden van de grote deleties. De meeste breukpunten waren echter wel geïmponeerd in of vlakbij DNA sequenties die zijn afgeleid van transposon elementen. Dergelijke elementen komen frequent voor in het humane genoom en beslaan ongeveer 37 % van het totale genoom. Analyse van de breukpunten van de grote deleties in de *BTK* en *Artemis* genen liet ook co-localisatie met transposon elementen zien. De hoge frequentie van grote deleties in *IGHM* en *Artemis* ging gepaard met veel transposon elementen in deze genen (41 % en 45 % t.o.v. 29 % voor *BTK*). Bovendien bleek dat juist het meest voorkomende type transposon element in het betreffende gen betrokken was bij de grote deleties. Deze waarneming werd bevestigd in een grote serie van 20 genen, die gemuteerd zijn bij bepaalde erfelijke ziekten. Daarom concluderen wij dat transposon elementen waarschijnlijk een belangrijke rol spelen in het optreden van grote deleties, en dan met name als ze relatief oververtegenwoordigd zijn in een bepaald gen. Hoe deze elementen grote deleties mediëren is vooralsnog onbekend, maar ze zouden een rol kunnen spelen in de structuur van het gen of extra gevoelig zijn voor het optreden van DNA breuken. Deze studie verschaft meer inzicht in het optreden van mutaties als oorzaak van erfelijke ziektes.

Bij een groot deel van de patiënten met een antistofdeficiëntie is (nog) geen genetische afwijking gevonden. In **Hoofdstuk V** beschrijven wij voor het eerst een genetische afwijking in het *CD19* gen bij 4 patiënten van 2 niet-gerelateerde families. Deze patiënten hebben normale aantallen B cellen in het bloed, maar deze cellen zijn niet in staat om voldoende te reageren op antigeen. Dit komt omdat het CD19 eiwit een belangrijke rol speelt bij het doorgeven van het activatie signaal aan de cel op het moment van de herkenning van antigeen met het Ig molecuul op het celoppervlak van de B cel. Wij hebben laten zien dat geïsoleerde B cellen van de CD19-deficiënte patiënten nauwelijks reageren op signalen via de Ig moleculen. Als gevolg hiervan hebben deze patiënten sterk verlaagde antistofconcentraties in het bloed en bleken ze niet in staat om voldoende specifieke antistoffen te maken na rabiës vaccinatie. Deze studie draagt bij aan verder begrip van antistofdeficiënties en in het onderscheiden van specifieke B-cel defecten in deze groep patiënten. Aangezien CD19 in een complex met CD21, CD81 en CD225 functioneert, zouden mutaties in die genen ook kunnen leiden tot een zelfde type antistofdeficiëntie.

In de reactie van een B cel op antigeen speelt proliferatie een belangrijke rol. Hoeveel celdelingen een B cel ondergaat in deze reactie is echter onbekend. Ook is de bijdrage van proliferatie van naïeve B cellen, die nog geen antigeen reactie hebben doorgemaakt, aan de omvang van de perifere B-cel populatie onbekend. In **Hoofdstuk VI** hebben we de mate van proliferatie van perifere B-cel subpopulaties onderzocht met een nieuwe DNA techniek. Met deze methode vonden we dat B cellen die recent uit het beenmerg zijn gekomen (transitionele B cellen) nog geen proliferatie hebben ondergaan. Rijpe naïeve B cellen hebben wel al 1 à 2 celdelingen doorgemaakt. Deze proliferatie is niet het gevolg van een reactie op antigeen, want deze cellen hebben nog geen aanvullende veranderingen in hun Ig genen aangemaakt. Marginale zone B cellen in de milt reageren zonder T-cel hulp op antigeen. Deze cellen kunnen ook in lymfklieren en bloed worden gevonden als “natural effector

B cellen”, en hebben 4 celdelingen doorgemaakt. Deze cellen bevatten wel veranderingen in hun Ig genen. De mate van proliferatie en Ig veranderingen waren echter nog groter in B cellen die een antigeen reactie met T-cel hulp hadden doorgemaakt (memory B cellen; 8 celdelingen). De T-cel afhankelijke B-cel reactie lijkt dus beduidend krachtiger te zijn dan de T-cel onafhankelijke B-cel reactie. De gemiddelde proliferatie van natural effector B cellen en memory B cellen was hoger bij volwassenen dan bij kinderen. Dit komt waarschijnlijk doordat een deel van deze cellen bij volwassenen meerdere keren een antigeen reactie heeft doorgemaakt. Deze studie verschaft nieuw inzicht in de bijdrage van proliferatie aan de opbouw van de perifere B-cel populatie en aan de antistof reactie tegen antigeen.

Dit proefschrift illustreert dat onderzoek naar fundamentele aspecten van B-celontwikkeling nieuwe inzichten oplevert betreffende het ontstaan van antistofdeficiënties. Aan de andere kant is gedetailleerd onderzoek van het B-celsysteem van patiënten met een antistofdeficiëntie buitengewoon belangrijk om nieuwe inzichten te verkrijgen in B-celontwikkeling. Zodoende benadrukt parallel onderzoek naar B-celontwikkeling en B-celdeficiënties de meerwaarde van kruisbestuiving tussen basaal en patiëntgebonden onderzoek.

DANKWOORD

De laatste loodjes wegen het zwaarst, en daar hoort in dit geval ook het dankwoord bij. Meer dan alle andere secties van een proefschrift is dit erg persoonlijk, en meer dan bij alle andere secties flitsen er allerlei gedachten en herinneringen door mijn hoofd. Bijna vijf jaar geleden begon ik aan dit onderzoek. Met dank aan Frank Staal kwam ik in contact met de afdeling Immunologie, waar ik nog voor mijn afstuderen een mijns inziens prachtig project kreeg voorgeschoteld binnen de groep van prof.dr. J.J.M. van Dongen, onder begeleiding van dr. M. van der Burg en in samenwerking met prof.dr. R. de Groot van de afdeling Kindergeneeskunde.

Als ik nu terug kijk denk ik dat hoe leuk het project mij toen ook al leek, de ervaringen die ik later heb opgedaan en de behaalde resultaten boven mijn verwachtingen zijn geweest. Dit was uiteraard te danken aan een gezamenlijke inspanning van vele mensen die ik bij deze graag wil bedanken voor hun onmisbare steun.

Mirjam, nog maar net gepromoveerd en begonnen als werkgroep leider van de primaire immuundeficiënties kreeg je mij onder je hoede. Vanaf het moment dat ik de afdeling bezocht stond je te popelen om te beginnen en dit enthousiasme duurt nog altijd voort. Bovendien kon ik altijd terecht met kleine en grotere problemen om deze samen op te lossen. Ik ben er zeker van dat jij nog vele promovendi zult begeleiden. Ik ben er dan ook nu al trots op de eerste te zijn geweest!

Beste Jacques, je was als mijn promotor enorm bevlogen en betrokken. Bovendien ben je een bijzonder kritische begeleider, maar ook zeer positief (met krul!) als je iets goed vindt. Hoewel je als hoofd van een grote unit met diverse onderwerpen altijd druk was in binnen- of buitenland, kon ik toch wanneer het nodig was direct contact met je opnemen, zelfs toen ik in San Diego zat. Ik heb dan ook veel van je mogen leren en hoop dat de komende jaren nog verder te kunnen doen.

Beste Ronald, de goede relatie en de gezamenlijke interesse van Jacques en jou in primaire immuundeficiënties hebben dit werk mogelijk gemaakt. De afgelopen jaren ben jij met name indirect bij mijn promotieonderzoek betrokken geweest. Het klinkt misschien vreemd, maar ik ben je daar juist heel erg dankbaar voor. Door de directe begeleiding in handen van Mirjam en Jacques te leggen, was de aansturing vanuit mijn oogpunt helder en heb ik nooit tussen twee vuren hoeven te zitten.

Tijdens mijn promotieonderzoek heb ik de mogelijkheid gekregen om een werkbezoek af te leggen in het lab van prof.dr. C. Murre aan de University of California, San Diego. Dit was voor mij een geweldige ervaring. Beste Kees, ik wil je graag hartelijk bedanken voor deze kans en voor het vertrouwen dat je me hebt gegeven. Hoewel je een goede groep leidt, ben je als een echte onderzoeker het liefst nog continue in het lab aan het werk. Dit gaf mij de kans om zowel conceptueel als praktisch gezien heel veel van je te leren. Het is dan ook een eer voor mij dat je in de kleine commissie zitting wilt nemen. In addition, I would like to thank Suchit Jhunjunwala. With mixed feelings I look back to all those hours we spent in the basement behind the microscope ('the beach'). It was tough, but thanks to your accuracy and great teamwork, we got the 10 kb probes to work.

Wim, hoewel we nooit aan een gezamenlijk project hebben gewerkt, heb ik zoveel van je geleerd. Bijna vier jaar hebben we een kamer gedeeld en back-to-back ons werk gedaan.

Tussendoor was er echter tijd om te reflecteren over ons werk, de immunologie, onderzoek in het algemeen en voetbal. Dankjewel hiervoor.

Helaas kan ik niet iedereen persoonlijk op deze plek bedanken. Wel wil ik graag iedereen van de afdeling Immunologie en in het bijzonder allen binnen de Unit Moleculaire Immunologie bedanken. In addition, I would like to thank the people from the Murre lab for their kindness and willingness to help me out when needed. Barbara en Sandra, jullie hebben me vanaf het begin met raad en daad bijgestaan in het lab. Hetzelfde geldt voor Edwin, ‘the sorter-guy’: echt leuk dat we al die sorts én de Ca^{2+} -flux aan de praat hebben gekregen! Dick de Ridder was onmisbaar voor de microarray analyse en scherpe commentaren op manuscripten. Ik hoop dat je ook wat van ons, biomedici, geleerd hebt. De secretariële ondersteuning van Bibi, van Wendy voor de lay-out van het proefschrift en van Marieke voor de figuren was onmisbaar. Ik vond het heel leuk (en leerzaam) om met Nicole en Corinne samen te werken. Corinne, dankjewel dat je nu ook mijn paranimf wilt zijn.

Ik wil graag prof.dr. H. Hooijkaas en prof.dr. C.J.M. van Noesel danken voor het kritisch doorlezen van mijn proefschrift als leden van de kleine commissie. Ook dank ik prof. dr. R. Benner, hoofd van de afdeling Immunologie, voor het mogelijk maken van dit onderzoek. Ik dank Rob, prof.dr. E.A.M. Sanders, dr. N.G. Hartwig en dr. A. Lankester voor de toezegging zitting te nemen in de grote commissie; ik kijk erg uit naar de verdediging.

Tot slot wil ik het thuisfront bedanken. Papa en Mama, jullie zijn er altijd voor me geweest en hebben me altijd gesteund, hoe abstract de onderzoeksonderwerpen ook werden. Zonder jullie steun was ik nooit zo ver gekomen en ik vind het erg fijn dat jullie er nog altijd voor me zijn. Rosalie, al jaren zijn we nu uit huis en volgens mij hebben die ons contact er alleen maar beter op gemaakt. Ik ben er dan ook trots op mijn zusje als paranimf naast me te hebben.

Menno

CURRICULUM VITAE

Menno Cornelis van Zelm

Geboren: 24 juni 1979 te Utrecht

Opleiding

- 1991 – 1997** Christelijk Gymnasium Utrecht
- 1997 – 1998** Propedeuse Biologie, Universiteit Utrecht
- 1998 – 2000** Bachelor of Science (*cum laude*), University College Utrecht, Universiteit Utrecht
- 1999 Semester studie aan de University of California, San Diego, USA
- 2000 – 2002** Master of Science, Biologie, Universiteit Utrecht
- 2000 Stage
'Inhibition of Degranulation in Permeabilized RBL-2H3'
Pharmacologie and Pathophysiologie, Utrecht Institute for Pharmaceutical Sciences (UIPS), Universiteit Utrecht
Supervisie: Dr. F.A.M. Redegeld
- 2000 – 2001 Stage
'The effect of one point mutation on the structure and stability of a protein'
Medicinal Chemistry, UIPS, Universiteit Utrecht
Supervisie: Dr. E.E. Moret
- 2001 – 2002 Stage
'Molecular genetic analysis of a family of β -catenin interacting proteins involved in hypodermal morphogenesis'
Hubrecht laboratory, Netherlands Institute for Developmental Biology, KNAW (Royal Netherlands Academy of Arts Sciences)
Supervisie: Dr. H.C. Korswagen
- 2002 Scriptie
'Regulation of Wnt signaling by cell-cell interactions in *C. elegans*'
Hubrecht Laboratory, Netherlands Institute for Developmental Biology, KNAW
Supervisie: Dr. H.C. Korswagen

- 2002 – 2007** Promotie-onderzoek bij de afdelingen Immunologie en Kinder-
geneeskunde van het Erasmus MC/Erasmus Universiteit Rotterdam
‘B-cell development and Primary Antibody Deficiencies’
Promotoren: Prof.dr. J.J.M. van Dongen, Prof.dr. R. de Groot
Copromotor: Dr. M. van der Burg
- 2005 – 2006 Werkbezoek
‘Visualization of Ig Gene Rearrangement Processes in Precursor-
B-cell Differentiation’
Division of Biological Sciences, University of California, San Diego,
USA
Supervisie: Prof.dr. C. Murre
