ABSTRACT

Purpose

To investigate the cerebrospinal fluid proteome of patients with pre-eclampsia and normotensive pregnant women, in order to provide a better understanding of brain involvement in pre-eclampsia.

Experimental design

98 cerebrospinal fluid samples (43 women with pre-eclampsia and 55 normotensive controls) were analyzed by LC-MS/MS proteome profiling. Cerebrospinal fluid was obtained during the spinal puncture before Caesarean delivery.

Results

Eight proteins were higher abundant and 17 proteins were lower abundant in patients with pre-eclampsia. The most significantly differentially abundant protein was protein AMBP (alpha-1-microglobulin/bikunin precursor). This finding was validated by performing an ELISA experiment ($p = 0.002$).

Conclusions and clinical relevance

The current study showed a clear difference between the protein profiles of cerebrospinal fluid from patients with pre-eclampsia and normotensive pregnant women. Protein AMBP is a precursor of a heme-binding protein that counteracts the damaging effects of free haemoglobin, which may be related to the presence of free hemoglobin in cerebrospinal fluid. Protein levels showed correlations with clinical symptoms during pregnancy and postpartum. To our knowledge, this is the first LC-MS/MS proteome profiling study on a unique set of CSF samples from (severe) pre-eclamptic patients and normotensive pregnant women.

INTRODUCTION

Worldwide, 2-8% of all pregnancies are complicated by pre-eclampsia (PE), a major cause of maternal and foetal morbidity and mortality (1, 2, 17). The disease presents as general endothelial damage and hence a multi-organ disorder, affecting the placenta, the mother's liver, kidneys, clotting system and heart. In severe cases of PE the maternal central nervous system (CNS) can be involved as well, which may result in major cerebrovascular complications such as eclampsia and stroke. Interestingly, PE may also lead to long-term brain pathology such as cognitive impairment and stroke (186-188). Brain complications of PE are suggested to be the result of a disturbed cerebral auto-regulatory response to the increased blood pressure in combination with endothelial cell dysfunction (189). Due to disruption of the blood-brain barrier (BBB), inflammatory cells and fluid penetrate the brain, causing oedema and cell death (8-11). The endothelial cells of the BBB differ from those in peripheral tissues. They have a low rate of endocytosis and are coupled by tight junctions to restrict the amount of para-cellular fluid. These functions ensure that not all blood constituents can pass freely into the extracellular space in the CNS (12).

We hypothesize that PE is associated with an abnormal adaptation of the BBB to the changed physiological and immunological state of pregnancy. The aim of this study was to investigate the cerebrospinal fluid (CSF) proteome of patients with PE and normotensive pregnant women by using high-resolution mass spectrometry.

MATERIAL AND METHODS

Pregnant women of 18 years and older who underwent a Caesarean delivery were recruited. Approval for the study was obtained from the Erasmus MC, University Medical Centre Research Ethics Board (MEC 2007-086). After written informed consent a CSF sample (one mL) was collected during the spinal anaesthesia procedure. The needle used during the spinal puncture was a 25 Gauge atraumatic needle. The CSF sample was collected before anaesthetics were administered. Within one hour the CSF samples were centrifuged and cells and debris were discarded. The CSF was aliquoted and stored immediately at -20 degrees Celsius (°C) and within 8 hours at -80 °C. Cases were defined as patients with PE who were admitted on the antenatal ward and in need of a Caesarean delivery. PE was defined as systolic blood pressure ≥ 140 mm Hg or diastolic blood pressure ≥ 90 mm Hg on at least two occasions 4 hours apart after 20 weeks of gestation or post-partum in combination with proteinuria (≥ 300 mg/24 hours or protein/creatinine ratio ≥ 0.3 mg) (37, 146). Controls were pregnant women without PE in need for a Caesarean delivery. Clinical data were obtained from the medical records of the study participants. General characteristics were statistically compared between study groups by using Mann-Whitney U tests data for (not normally

distributed) continuous data and Chi-square tests or Fisher's exact for categorical data. Clinical postnatal data were available up to one year postpartum. Neurological symptoms postpartum were defined as complaints of headache, visual disturbances, concentration problems and other cognitive complaints.

Samples were processed in two batches, using the CSF digestion and mass spectrometry measurement protocol previously published (190). In brief, from each CSF sample, 20 μL was added to 20 μL of 0.2% Rapigest (Waters, Milford, MA) in 50 mM ammonium bicarbonate buffer. After 30 min incubation periods with 1,4-dithiothreitol (60 °C) and, subsequently, iodoacetamide (37 °C), 6 μL 0.1 $\mu\text{g}/\mu\text{L}$ gold-grade trypsin (Promega, Madison, WI)/3 mM Tris-HCl (pH 8.0) was added to each sample. The samples were incubated overnight at 37 °C. To adjust the pH of the digest to $\text{pH} < 2$, trifluoroacetic acid (TFA) was added to the mixture prior to the final incubation step at 37 °C for a duration of 45 minutes to stop the enzymatic digestion reaction. Subsequently the samples were measured alternating between PE and control samples.

Mass spectrometry measurements were performed on a Ultimate 3000 nano LC system (Dionex, Germering, Germany) online coupled to a hybrid linear ion trap/Orbitrap MS (LTQ Orbitrap XL; Thermo Fisher Scientific, Germany). One μL digest (i.e. 0.4 μL CSF) was loaded on to a C18 trap column (C18 PepMap, 300 μm ID \times 5 mm, 5 μm particle size, 100 Å pore size; Dionex, The Netherlands) and desalted for 10 minutes using a flow rate of 20 $\mu\text{L}/\text{min}$ 0.1% TFA. Then the trap column was switched online with the analytical column (PepMap C18, 75 μm ID \times 150 mm, 3 μm particle and 100 Å pore size; Dionex, The Netherlands) and peptides were eluted with following binary gradient: 0%–25% solvent B in 120 min and 25%–50% solvent B in further 60 minutes, where solvent A consist of 2% acetonitrile and 0.1% formic in water and solvent B consists of 80% acetonitrile and 0.08% formic acid in water. Column flow rate was set to 300 nL/min. For MS detection a data dependent acquisition method was used: high-resolution survey scan from 400–1800 Th. was performed in an Orbitrap (value of target of automatic gain control AGC 10^6 , resolution 30,000 at 400 m/z; lock mass was set to 445.120025 u (protonated $(\text{Si}(\text{CH}_3)_2\text{O})_6$)). Based on this survey scan the 5 most intensive ions were consecutively isolated (AGC target set to 10^4 ions) and fragmented by collision-activated dissociation (CAD) applying 35% normalized collision energy in the linear ion trap. After precursors were selected for MS/MS, they were excluded for further MS/MS spectra for 3 minutes.

The raw data were pre-processed using the Progenesis LC-MS software package (version 4.0, Nonlinear Dynamics, Newcastle-upon-Tyne, United Kingdom). Peptides were identified and assigned to proteins by exporting features, for which MS/MS spectra were recorded, using the Bioworks software package (version 3.2; Thermo Fisher Scientific, Germany; peak picking by Extract_msn, default settings). The resulting .mgf file was submitted to Mascot (version 2, Matrix Science, London, United Kingdom) for identification to interrogate the UniProt-database (release 2013_07; taxonomy: Homo sapiens, containing 20265

sequences). Only ions with charge states between +2 and +8 were considered and only proteins with at least two unique peptides (Mascot ions score > 25, (i.e. a peptide probability cut off value of 0.01) assigned to them were accepted as true identifications. Modifications: carbamidomethylation of cysteine was set as fixed and oxidation of methionine as variable modification, allowing a maximum of 2 missed cleavages. Mass tolerance for precursor ions was set to 10 ppm and for fragment ions at 0.5 Da. The Mascot search results were imported into the Progenesis software to link the identified peptides to the detected abundances of these peptides. The peptide abundances were normalized to the total ion current to compensate for experimental variations using an algorithm available in the analysis software. Subsequently the data were exported in Excel format.

The raw abundances of all identified peptides were compared between the groups of samples by performing an unpaired 2-tailed t-test on all individual peptides. Proteins were deemed to be significantly differentially abundant between the groups if they passed a set of three separate criteria: 1- 50% or more of the peptides of the protein had a low p-value ($p < 0.05$); 2- 30% of the peptides of the protein had a very low p-value ($p < 0.01$); 3- 75% or more of the peptides of the protein must be altered in the same direction between the groups (190-192). We determined the statistical background level by performing a permutation test using all samples and all identified peptides. The random permutation test, on the dataset with randomized sample group assignment, was repeated 1000 times through which, the resulting thresholds were saved.

Following the results of this experiment three validation experiments were performed. A commercially available enzyme-linked immunosorbent assay (ELISA) for *in vitro* quantitative measurements of foetal haemoglobin (Cloud-clone Corp, USA) and an ELISA for *in vitro* quantitative measurement of protein AMBP (alpha-1-microglobulin/bikunin precursor, LifeSpan BioSciences, Inc., USA) were performed. The AMBP concentrations were calculated by generating a four-parameter logistic standard curve (CurveExpert v1.3, 2013, supplementary figure 1).

Another validation experiment for A1M (alpha-1-microglobulin), a derivative protein of AMBP, was performed. A1M was measured with an in-house RIA method, as previously described by Olsson et al (193). Briefly, the analysis was performed by mixing goat antiserum against human A1M (diluted 1:6000) with ^{125}I -labelled A1M (≈ 0.05 pg/ml) and unknown patient samples or calibrator A1M concentrations. After incubating the samples overnight at RT, antibody-bound antigen was precipitated, after which the ^{125}I -activity of the pellets was measured in a Wallac Wizard 1470 gamma counter (Perkin Elmer Life Sciences).

Statistical comparison of AMBP and A1M values was performed by using the Student's T-test and ANOVA. Not normally distributed data (AMBP) were log transformed before testing. Correlations for gestational age at sampling and with neurological symptoms were tested by using Pearson's correlation test.

RESULTS

LC-MS/MS proteome profiling

Cerebrospinal fluid samples from 43 patients with PE and 55 normotensive pregnant women were obtained for proteomics analysis. Most general characteristics did not significantly differ between the groups, except for parity, gestational age at sampling, PE in a previous pregnancy and a Caesarean delivery in the obstetric history (table 1). As a result of the definition of PE, women with PE had a higher blood pressure (median 170/110 mmHg) than normotensive controls (median 122/77 mmHg).

A total of 3473 peptides were identified, corresponding to 457 unique proteins. Of the 3473 peptides 317 peptides had p-values below 0.01. The number of background hits obtained by permutation was 49.6 ± 51.3 , indication that the number of peptides found with low p-values in the true analysis was well above expected background levels (supplementary figure 2).

Of the 457 proteins, twenty-five were differentially abundant between cases and controls by using the above mentioned selection criteria. Eight proteins were higher abundant and 17 proteins were lower abundant in the CSF from patients with PE (table 2). Subtype analyses for HELLP-syndrome, severe PE and early-onset PE (EOPE) did not result in additional differentially abundant proteins.

Validation experiments

The most significantly differentially abundant protein was protein AMBP. A validation experiment (ELISA) in 19 randomly chosen normotensive pregnant controls and 20 patients with PE of the same study group was performed. The level of protein AMBP was significantly higher in patients with PE versus normotensive controls (15.24 (IQR 11.42-23.76)) ng/ml versus 10.88 (IQR 7.74-12.92) ng/ml, $P = 0.002$, table 3 and figure 1). When we subdivided the cases in early-onset PE (EOPE) and late-onset PE (LOPE), a significant difference was found in the AMBP-level of patients with EOPE and normotensive women (17.92 (IQR 12.21-3.17) ng/ml versus 10.88 (IQR 7.74-12.92) ng/ml, $p = 0.001$).

Protein AMBP is a precursor of A1M and bikunin. We additionally quantified the A1M-level in 47 CSF samples of patients with PE and 52 CSF samples of normotensive controls from the same study group (in-house RIA method). A1M was significantly higher in PE compared to controls (0.35 (± 0.1) ng/ml versus 0.27 (± 0.14) ng/ml, $p = 0.012$). We found no correlation of A1M-levels with gestational age at sampling.

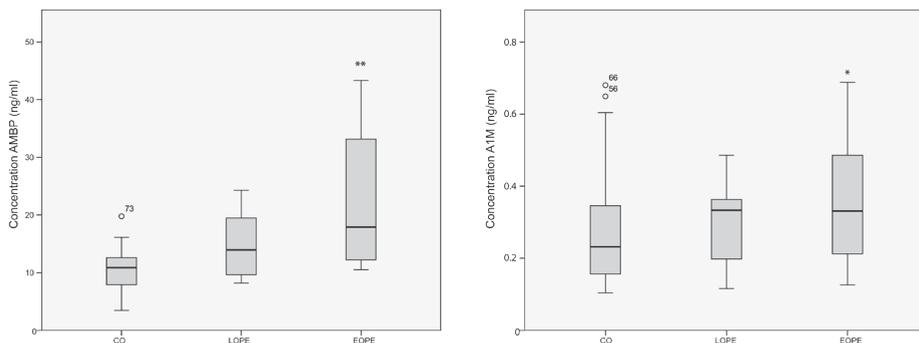

Free haemoglobin was identified in the CSF in both cases and controls. In order to exclude that the presence of haemoglobin was caused by a traumatic puncture, we repeated our experiment in exactly the same manner in four other normotensive pregnant women. We collected the first, fifth and tenth drop of CSF. Again, free haemoglobin proved to be present in these samples, regardless of the order of the aliquots collected. When the presence of

Figure 1. Boxplots of AMBP and A1M levels

** $P = 0.001$ (EOPE vs. CO). * $P = 0.011$ (EOPE vs. CO). IQR = interquartile range, CO = control, EOPE = early onset pre-eclampsia, LOPE = late onset pre-eclampsia, A1M = alpha-1-microglobulin; AMBP = alpha-1-microglobulin/bikunin precursor.

haemoglobin in the CSF samples is due to contamination, we would expect the abundance of haemoglobin the highest in the first drop before decreasing to the lowest amount in the 10th drop.

In order to find out if the free haemoglobin detected was either of maternal or foetal origin an ELISA for foetal haemoglobin (HbF) was performed. The detection limit of this immunoassay was 0.55 ng/ml. We were not able to detect HbF in the CSF samples, because the resulting values were lower than the detection limit of the assay.

Clinical symptoms during pregnancy

In order to investigate the clinical implications of these findings we studied neurological symptoms of the study participants and their relation to AMBP- and A1M-levels.

In the PE group 58.8% of the participants reported complaints of headache, compared to 12.1% of the normotensive pregnant women. Twenty percent of the patients with PE reported visual complaints, which was 5.2% in the group of normotensive pregnant women (table 1).

A positive correlation was found between visual symptoms and AMBP-level in the whole group ($p < 0.01$) (supplementary figure 3).

In the subgroup of severe PE, AMBP- and A1M-levels tend to be lower in women who reported neurological symptoms than in women without neurological symptoms (lnAMBP: 2.9 ± 0.75 versus 3.2 ± 0.34 , A1M: 0.33 ± 0.20 ng/ml versus 0.41 ± 0.14 ng/ml), though this difference was not statistically significant (supplementary figure 4).

Clinical symptoms postpartum

37.3% percent of PE patients (all severe PE) reported neurological symptoms from 6 weeks to 1 year after delivery (supplementary table 2), while none of the normotensive women reported these symptoms during their standard 6 weeks check-up after delivery ($p < 0.0001$).

DISCUSSION

The current study showed a clear difference between the protein profiles of cerebrospinal fluid from patients with PE and normotensive pregnant women. To our knowledge, this is the first study that performed high-resolution mass spectrometry on CSF samples of pregnant women with and without PE. Normal pregnancy is associated with neurophysiological adaptations of the brain, including decreased inhibitory gamma-aminobutyric acid type A (GABAA) receptor subunit expression in the cerebral cortex that lowers seizure threshold (194). Studies have previously shown that pregnancy is a state with higher neuronal network excitability and a lower seizure threshold. This may be due to high levels of neurosteroids during pregnancy (194-197).

In addition to this, the BBB is suggested to play an important role in this process. Cipolla and co-workers investigated the function of the BBB in non-pregnant versus late-pregnant rats. They found that pregnancy caused a significant increase in BBB permeability following acute hypertension (198).

Protein AMBP and free haemoglobin

The most significantly differentially abundant protein, is protein AMBP, which was higher abundant in PE. Protein AMBP is a precursor of A1M and bikunin. A1M has been related to pregnancy and PE in several studies. Elevated serum levels of HbF and A1M in first trimester have been described to be predictive of subsequent development of PE and were also correlated with the severity of the disease (26). In an *ex-vivo* placenta perfusion experiment, free haemoglobin was shown to damage the blood-placenta barrier by inducing oxidative stress. Free Hb caused structural damage to the placenta, signs of oxidative stress similar to what have been described in the PE placenta. By adding the heme-binding protein A1M to the system, the structural damage was prevented and leakage over the placenta barrier was inhibited (199, 200). It is hypothesized that the pathogenesis of PE involves an

increased expression of HbF in the placenta which due to barrier damage, leaks into the maternal circulation, causes oxidative stress and further endothelial damage (200). A1M is a heme-binding protein that is higher abundant and counteracts the damaging effects of free haemoglobin, shown to be elevated in PE. Free Hb might cause damage to the BBB in a similar way as described for the blood-placenta barrier. A similar process occurs in cerebral haemorrhage in preterm infants. Fragments of Hb cause cell death following intraventricular haemorrhage and upregulation of heme-scavenging proteins reduce the damage to the infants brain (201, 202). A recent mass spectrometry study showed protein AMBP also to be elevated in plasma of patients with PE, before the manifestation of clinical disease (203). Our findings are in line with these studies, which we showed for the first time in maternal CSF. Because the brain during this disorder is at risk for damage, these proteins may be upregulated.

Interestingly, when we only look in the subgroup of severe PE, AMBP- and A1M-levels tend to be lower in women who reported neurological symptoms than in women without neurological symptoms, taking into account that levels in PE were still higher than those in normotensive pregnancy, although this difference was not statistically significant. AMBP and A1M are upregulated in PE, but the upregulation and protective effect of AMBP/A1M for the CNS may fail in cases with severe PE who still report neurological symptoms. A possible explanation may be that these women are not able to oppose the toxic effects of PE properly. However, this cannot be proved with our data, since this was no functional study of the BBB. What makes it difficult is that PE has a heterogeneous phenotype. The pathophysiological process in the brain is complex and differs from patient to patient. This may also explain the variation of AMBP and A1M-levels in the PE-group.

Only a few previous studies investigated CSF of pregnant women by low-resolution mass spectrometry (204-210). Norwitz et al. identified nanomolar amounts of free haemoglobin in CSF of pregnant women (n=22) (209). The method of identification used in this study was SELDI-TOF mass spectroscopy. A significantly higher free haemoglobin concentration was found in the CSF in patients with severe PE than in the CSF from mild PE or controls. They stated that this toxic free haemoglobin may have a role in the cerebrovascular injuries seen in patients with severe PE. Although in line with the results described by Norwitz *et al.*, it is a remarkable finding that free haemoglobin is present in CSF in all pregnant women, as shown in the present study. From mass spectrometry data of non-pregnant healthy patients we know that CSF contains no or a very low content of free haemoglobin. None of our CSF samples contained macroscopically visible haemoglobin. The needle used in our study (25 Gauge) is not expected to cause more traumatic punctures than the needle (22 Gauge) commonly used during lumbar punctures performed by a neurologist. Furthermore, the total amount of proteins did not differ from the total amount of proteins normally found in CSF of non-pregnant subjects, which supports the idea that the presence of free haemoglobin was not likely caused by a traumatic puncture, but this event cannot be completely ruled out.

Other differentially abundant proteins in CSF of patients with PE

In this section we will briefly describe the other differentially abundant proteins and their possible relation to PE (table 2). Alpha-1-acid glycoprotein is an acute phase protein that increases during inflammation and protects the endothelium. It was previously identified as a predictive biomarker for PE in urine (211, 212). Alpha-1-acid glycoprotein is constitutively expressed by human microvascular endothelial cells (213). Interestingly, previous studies identified Alpha-1-acid glycoprotein as a protein, which alters the BBB integrity in inflammatory-related diseases (214-216). Alpha-1-antichymotrypsin is a high abundant plasma protein that is synthesized by the liver and by trophoblast cells. In previous studies, serum and urine levels of this protein were significantly higher in patients with PE. Moreover, this protein was found to be a possible predictor of PE (217, 218). Retinol-binding protein-4 carries retinol in the blood and is higher abundant in patients with an impaired glucose regulation, obesity, diabetes, polycystic ovary syndrome and cardiovascular disease, in fact all risk factors for PE. One previous study showed an association with early-onset PE (219), though another study did not identify significantly altered serum levels in PE (220). Also, insulin-like growth factor 2 showed a positive correlation with PE in a prospective cohort study (221). Histidine-rich glycoprotein is a protein interacting with angiogenesis and the coagulation system. It acts as a negative acute phase reactant and its plasma levels are reduced during the last trimester of pregnancy (222, 223). The last two higher abundant proteins in the CSF were Lumican and Alpha-1-B glycoprotein. These proteins have not previously been correlated to PE.

The lower abundant proteins that were found in PE CSF, (brain acid soluble protein 1, cadherin-13, neurosecretory protein VGF, neurocan core protein, neuronal cell adhesion molecule, seizure-6 like protein, limbic system-associated membrane protein and neuroserpin) are not previously known to have an association with PE. Most of them have a specific function in neuronal cell adhesion, neural cell growth and interaction. It has been reported previously that decrease of neurological proteins is for instance observed in multiple sclerosis.

A major strength of our study is that we used a unique set of CSF samples from (severe) pre-eclamptic patients and normotensive pregnant women analysed by using high-resolution mass spectrometry. A limitation is that the cases and controls differed in parity and gestational age. However, the difference in gestational age is unavoidable when studying severe early-onset pre-eclamptic patients. Uncomplicated controls are rarely delivered by Caesarean delivery before 37-38 gestational weeks. Another limitation is that the finding that the CSF proteome of patients with PE differed from normotensive controls may be related to the fact that during the spinal puncture most of the PE patients received intravenous administration of magnesium sulphate (77%) and nifedipine (69%), respectively with a neuroprotective and anti-hypertensive effect. Also, most women in the PE group (77%) received antepartum corticosteroids for foetal lung maturation.

A third limitation is that we were not able to compare our data with the CSF proteome of non-pregnant women. Having CSF samples of this group would be helpful in better understanding the effect on the BBB of pregnancy itself. This is a challenge for future research, since it is hard to collect these kinds of samples. From an ethical point of view, CSF of healthy women without neurological diseases in the reproductive age can only be collected during spinal anaesthesia procedures for standard care. In our situation very few of these women receive spinal anaesthesia for operative procedures.

CONCLUDING REMARKS

There is a clear difference between the protein profiles of cerebrospinal fluid from patients with PE and normotensive pregnant controls. The finding that free haemoglobin was present in the CSF of both normotensive and hypertensive women may be explained by a different BBB permeability during pregnancy. This suggests that pregnancy itself makes the brain more vulnerable to cerebral complications, which is then aggravated in PE when protective proteins such as A1M are upregulated. However, the function of the BBB is complex and how this exactly functions during human pregnancy and PE needs to be further elucidated.
