Abstract

In many tropical areas schistosomiasis is a major health problem causing hepatosplenic, intestinal or urogenital complaints. Hepatosplenic schistosomiasis mansoni is also characterized by blood coagulation abnormalities. Liver pathology plays a role in the development of haemostatic changes and the parasitic infection may directly affect coagulation. However, these contributing factors cannot be studied separately in hepatosplenic schistosomiasis infections. This pilot study provides insight in haemostatic changes in urinary schistosomiasis by studying coagulation parameters in schistosomiasis haematobium-infected Gabonese schoolchildren. Selection on urinary schistosomiasis patients without hepatosplenic complaints allows for the investigation of the direct effects of the parasite on haemostasis. Levels of von Willebrand Factor (VWF) antigen, active VWF and osteoprotegerin were elevated, indicating inflammation-mediated endothelial activation. In contrast to hepatosplenic schistosomiasis, thrombin–antithrombin complex and D-dimer levels were not affected. Despite its small sample size, this study clearly indicates that Schistosoma haematobium directly alters the activation status of the endothelium, without initiation of coagulation.

Introduction

The tropical disease schistosomiasis is caused by blood-dwelling parasites of the Schistosoma genus. The major disease-causing species in humans are Schistosoma mansoni, Schistosoma haematobium and Schistosoma japonicum (Colley et al., 2014). With almost 800 million people at risk of infection, schistosomiasis is the second major parasitic disease after malaria (Steinmann et al., 2006).

The various species of Schistosoma reside in blood vessels at different locations in the body, and these specific locations determine pathology. Schistosoma mansoni and S. japonicum reside in the mesenteric plexus, and chronic infection results in the development of intestinal or hepatosplenic schistosomiasis, affecting intestine, liver and spleen (Colley et al., 2014). In contrast, S. haematobium resides in the perivesicular plexus. Infection with this species results in urogenital schistosomiasis, affecting mainly the urogenital tract, although hepatic disease may occur in severe infections (Cheever et al., 1977; Colley et al., 2014).

In addition to intestinal and hepatic disease, the blood coagulation system is affected in schistosomiasis mansoni patients (Mebius et al., 2013). These individuals are prone to bleeding as a result of coagulation-factor deficiencies, and often have reduced platelet counts (reviewed by Tanabe, 2003). Several factors are presumed to contribute to the loss of coagulation factors and platelets. First, the consumption of coagulation factors through the continuous activation of coagulation may be involved, since markers of active coagulation, such as thrombin–antithrombin (TAT) complexes, and markers of fibrinolysis, such as D-dimers, are both elevated in these patients. This activation of coagulation can be induced by the parasite itself, but it is also assumed that immune responses to schistosomes play a role in the development of haemostatic abnormalities in hepatosplenic schistosomiasis mansoni – for example, through stimulation of monocyte-tissue-factor expression (Amer & Amer, 2002). Second, the majority of coagulation factors are synthesized by the liver. Therefore, impaired liver function, resulting in reduced hepatic synthesis or clearance of activated coagulation factors, could contribute to the bleeding phenotype. It remains challenging to unravel the contribution of the parasite and liver damage...
to the development of haemostatic abnormalities in hepatosplenic schistosomiasis mansoni patients, since these factors cannot be separated in hepatosplenic disease.

This pilot study aims to elucidate the contribution of the parasite to the development of coagulation abnormalities in *Schistosoma* infections by studying haemostatic parameters in schoolchildren infected with *S. haematobium*. Since *S. haematobium* infections primarily cause urogenital schistosomiasis, strict selection on *S. haematobium*-infected individuals without hepatosplenicmegaly limits the influence of impaired hepatic function and allows investigation of the effect of only the parasitic infection on the development of coagulation abnormalities.

**Materials and methods**

**Participants and sample collection**

Ten schoolchildren with non-hepatosplenic schistosomiasis haematobium and four healthy controls without *S. haematobium* infection were recruited at the Centre de Recherches Médicales de Lambaréné (CERMEL), Lambaréné, Gabon. The study was approved by the CERMEL Institutional Ethics Committee (CEI, CEI-MRU 002 26/1/2016). Participants were schoolchildren without hepatosplenic complaints from Zilé-PK15 areas – *S. haematobium*-endemic areas surrounding Lambaréné (Ateba Ngaa et al., 2014). The presence of possible asymptomatic other infectious diseases that could affect haemostasis, such as malaria, were not investigated, but if present among the included participants these asymptomatic infections are expected to be evenly distributed between participants with and without urinary schistosomiasis. Informed consent was obtained from the parents or legal guardians of all children, and all infected individuals received treatment with praziquantel after sample collection. Venous blood was analysed with the Pentra 60 analyser (Horiba, Kyoto, Japan). Citrated platelet-poor plasma was obtained by twofold centrifugation of citrated blood at 2000*g for 15 min. Citrated plasma was aliquoted and stored at −80°C.

**Determination of *S. haematobium* infection**

Circulating anodic antigen (CAA) levels were determined in 20 µl citrated plasma with the wet reagent SCA20 (standard serum/plasma CAA test on 20 µl trichloroacetic acid (TCA) extract) lateral flow assay, as described by Corstjens et al. (2014). Samples were treated with 4% TCA to remove interfering components. CAA levels were calculated with a four-parametric curve-fitting method, using a standard dilution curve of the TCA-soluble fraction of schistosome adult worm antigen (AWA-TCA), which contains approximately 3% (w/w) CAA. The lower detection limit of the SCA2A0 was 150 pg/ml AWA-TCA (≈5 pg CAA/ml). Participants were considered positive when CAA levels were above 5 pg/ml. In addition, for all participants a midstream urine sample was collected during the daytime and at least 10 ml urine was passed through a 12.0 µm polyamide N-filter (Millipore, Billerica, MA, USA). *Schistosoma haematobium* eggs were detected by microscopic examination.

**Enzyme-linked immunosorbent assay**

Levels of D-dimer were measured in plasma with the Technozym D-dimer ELISA kit (Stago BNL, Leiden, The Netherlands) according to the manufacturer’s instructions. Levels of von Willebrand Factor (VWF) antigen (VWF:ag), active VWF, ADAMTS-13 antigen (ADAMTS-13:ag), osteoprotegerin (OPG) and TAT complexes were measured in plasma with ELISA. Ninety-six-well or 384-well white Maxisorp microtitre plates (Thermo Scientific, Roskilde, Denmark) were coated overnight at 4°C with polyclonal rabbit-anti-human VWF (0.775 µg/ml; A0082; DAKO, Carpinteria, CA, USA), AU/VWFa-11 nanobody (Hulstein et al., 2005) (1.98 µg/ml, D053 (0.5 µg/ml; Sanquin, Amsterdam, The Netherlands), mouse-anti-human OPG/ TNFRSF11B (1 µg/ml; R&D Systems, Minneapolis, MN, USA) or sheep-anti-human Thrombin (1 µg/ml; Stago BNL, Leiden, The Netherlands) in coating buffer (40 mM sodium carbonate, 35 mM sodium bicarbonate, 3 mM sodium azide, pH 9.6). Plates were washed four times with washing buffer (phosphate-buffered saline (PBS; ThermoFisher Scientific, Waltham, MA, USA), 0.05% Tween20, pH 7.4) between all incubation steps, and blocked for one hour at room temperature with blocking buffer (PBS, 1% bovine serum albumin (BSA), pH 7.4). Citrated plasma and standards were diluted in blocking buffer: 125-fold for VWF:ag ELISA, five- and tenfold for active VWF ELISA, 40-fold for ADAMTS-13:ag ELISA and fourfold for OPG and TAT ELISAs, and incubated for one hour at room temperature. Used standards were serial dilutions of normal pooled plasma (Sanquin, Amsterdam, The Netherlands) with a known concentration of VWFag for VWF:ag and ADAMTS-13:ag; normal pooled serum with known concentrations of TAT and OPG for TAT and OPG ELISAs and VWF-depleted plasma (Affinity Biologicals, Ancaster, Canada) supplemented with recombinant R1341Q-VWF for active VWF ELISA. Following sample incubation, the plates were incubated at room temperature for one hour with the following detection and secondary antibodies diluted in blocking buffer: peroxidase-conjugated rabbit-anti-human VWF (0.325 µg/ml), peroxidase-conjugated rabbit-anti-human VWF (1.2 µg/ml), biotinylated polyclonal sheep-anti-human ADAMTS-13 (0.25 µg/ml; R&D Systems, Minneapolis, MN, USA) and streptavidin-mono-horseradish peroxidase (HRP) (0.83 µg/ml; DAKO, Carpinteria, CA, USA), biotinylated goat-anti-human OPG/TNFRSF11B (100 ng/ml; R&D Systems, Minneapolis, MN, USA) and streptavidin-mono-HRP (0.25 µg/ml), and peroxidase-conjugated sheep-anti-human antithrombin (0.5 µg/ml; Stago BNL, Leiden, The Netherlands). ELISAs were developed with SuperSignal West Pico Chemiluminescent Substrate (ThermoFisher Scientific, Waltham, MA, USA) and luminescence was detected with the Synergy2 ELISA reader (BioTek, Winooski, VT, USA). Antigen concentrations were calculated with a five-parametric curve-fitting method, using a dilution curve of the standard. The lower detection limits of the ELISAs were: 6.8 ng/ml (VWF:ag), 16 ng/ml (active VWF), 1.6% (ADAMTS-13:ag), 10.6 pg/ml (OPG) and 2.8 pM (TAT).

**Ristocetin co-factor activity assay**

Citrated plasma was diluted sevenfold in imidazole buffer (100 mM imidazole, 100 mM NaCl, pH 7.4). A standard dilution curve was prepared of diluted normal pooled plasma. Then, 200 µl BC von Willebrand Reagent (Siemens Healthcare, Erlangen, Germany) was added to the 70 µl sample in a 96-well clear Maxisorp microtitre plate. Following 10 min incubation at 37°C and 20 min incubation at room temperature, to allow platelet aggregates to precipitate, 100 µl of the mixture was transferred to a new plate and non-aggregated platelets were measured at
350 nm. Ristocetin co-factor activity (VWF:RCo) was calculated with a five-parametric curve-fitting method, using a dilution curve of the standard. The lower detection limit of the assay was 3% VWF:RCo.

ADAMTS-13 activity measurement

ADAMTS-13 activity was measured in a kinetic assay using the fluorescence resonance energy transfer substrate VWF73 (FRETS-VWF73; Peptide Institute, Osaka, Japan) as previously described (Kokame et al., 2005). Samples were tenfold diluted in Tris buffer (5 mM Tris, 25 mM calcium chloride, 0.005% Tween20, pH 6.0). FRETS-VWF73 was added to a final concentration of 2 µM and fluorescence ($\lambda_{ex}$ 340 nm, $\lambda_{em}$ 450 nm) was measured in a 96-well black microtiter plate (Thermo Scientific, Roskilde, Denmark) every 30 s for one hour at 30°C with a Spectramax M2e device (Molecular Devices, Sunnyvale, CA, USA).

Statistical analysis

Analyses were done using PRISM software (GraphPad, San Diego, CA, USA, version 6.01). Infected and non-infected control groups were compared using the Mann–Whitney U-test and $P \leq 0.05$ was considered statistically significant.

Results and discussion

We included ten schoolchildren with schistosomiasis haematobium and four healthy children from S. haematobium-endemic,

### Table 1. Participant characteristics.

|                                 | Schistosoma haematobium-infected children | Controls |
|                                 | Mean (SD) | Mean (SD) |
| Number, $n$                     | 10        | 4         |
| Age (y), mean (SD)              | 11 (3)    | 8 (1)     |
| Male, $n$ (%)                   | 5/10 (50) | 3/4 (75)  |
| Weight (kg), mean (SD)          | 37 (13)   | 27 (2)    |
| Height (m), mean (SD)           | 1.47 (0.16) | 1.34 (0.03) |
| CAA (pg/ml), mean (SD)          | 2166 (3062) | 0 (0)     |
| Egg count positive, $n$ (%)     | 9/10 (90) | 0/4 (0)   |
| Egg count/10 ml urine, mean (SD)| 272 (289) | 0 (0)     |

| Parasitic co-infections, $n$ (%) |  |
| Ascaris                           | 0/8 (0) | 0/3 (0) |
| Ancylostoma                       | 0/8 (0) | 0/3 (0) |
| Trichuris                         | 3/8 (38) | 1/3 (33) |
| Missing                           | 2       | 1       |

| Whole blood analysis, mean (SD)   |  |
| Haemoglobin (g/dl)                | 11.0 (1.9) | 11.7 (1.3) |
| Platelets ($n \times 10^9/l$)     | 253 (66)  | 322 (54)  |
| Lymphocytes ($n \times 10^9/l$)   | 4.2 (0.9)  | 3.6 (0.5)  |
| Monocytes ($n \times 10^9/l$)     | 0.7 (0.2)  | 0.9 (0.2)  |
| Splenomegaly, $n$ (%)             | 1/9 (11)   | 0/4 (0)    |
| Hepatomegaly, $n$ (%)             | 0/9 (0)    | 0/4 (0)    |

Data are number with percentage or mean with SD. CAA, circulating anodic antigen; SD, standard deviation.
rural areas surrounding Lambaréné (Gabon) (table 1). Infection status was based on CAA levels in plasma (Corstjens et al., 2014) combined with the detection of viable eggs in urine, since the detection of eggs in urine as the only method to confirm infection has a low sensitivity (Colley et al., 2014). As expected, a positive correlation was found between the number of eggs detected by urine filtration and the concentration of CAA in plasma (not shown). Hepatomegaly was absent in all studied individuals and splenomegaly was absent in nine out of ten infected and in all non-infected individuals; therefore, all infected children were characterized as strictly urogenital schistosomiasis haematobium.

In hepatosplenic schistosomiasis mansoni, levels of VWF:ag are highly elevated and inversely correlate with platelet counts, as patients experience thrombocytopenia (Correia et al., 2009). To determine the effect of Schistosoma infection on VWF levels in urinary schistosomiasis, we determined VWF:ag, active VWF and VWF ristocetin cofactor activity (VWF:RCo) in our study participants. VWF is secreted by endothelial cells and circulates in a globular conformation in which the platelet-binding A1-domain is inaccessible (Hulstein et al., 2005). Under blood flow, VWF unfolds and adopts an active platelet-binding conformation (active VWF) that can be detected using the AU/VWFa-11 nanobody (Hulstein et al., 2005). Besides flow, ristocetin can also be used to unfold VWF and study its binding to platelets (VWF:RCo). Levels of VWF:ag and active VWF were significantly increased in infected children compared to non-infected controls ($P = 0.002$ and $P = 0.004$, respectively; see fig. 1a, b). The elevated VWF:ag levels indicate either increased secretion or reduced breakdown of VWF. The proportion of VWF that is active (percentage of active VWF) is slightly decreased in infected children compared to non-infected individuals, indicating that increased conformational activation of circulating VWF is not responsible for the observed increase in active VWF ($P = 0.024$; fig. 1c). In contrast to increased VWF:ag and active VWF levels, VWF:RCo was low or absent in all individuals ($P = 0.6234$; fig. 1d). As all individuals had normal platelet counts ($253 \pm 66) \times 10^9/l$ and $(322 \pm 54) \times 10^9/l$ in infected and non-infected individuals, respectively ($P = 0.1063$) and plasma from Dutch controls showed normal VWF:RCo activity (data not shown), this observation cannot be explained by low platelet counts or poor performance of the VWF:RCo assay. Reduced or absent platelet aggregation on ristocetin in Africans compared to Europeans has been reported previously (Dupuy et al., 1978; Buchanan et al., 1981). Reduced platelet function was attributed to a plasma inhibitor of ristocetin-induced platelet aggregation (Dupuy et al., 1978; Buchanan et al., 1981), though genetic polymorphisms in VWF could also affect the ristocetin-based activity.

Fig. 1. Haemostatic parameters in Schistosoma haematobium-infected schoolchildren. VWF:ag levels (a), active VWF levels (b), ADAMTS-13:ag levels (e), OPG levels (g), TAT levels (h) and D-dimer levels (i) were measured with ELISA in citrated plasma of S. haematobium-infected schoolchildren and non-infected controls. Percentage of active VWF (c) was calculated with the determined active VWF and VWF:ag levels. VWF:RCo (d) was determined with the BC von Willebrand Reagent. ADAMTS-13 activity (f) was determined with the FRET-S-VWF73 assay. Dotted lines indicate normal ranges (a, d) or cut-off values (g–i). Statistical analysis was performed with a Mann–Whitney U-test. $P \leq 0.05$ was considered statistically significant. Abbreviation: ns, not significant.
assay (Flood et al., 2010). It is, however, unclear whether these accounted for the observed low VWF:RCo activity in our study. In summary, in urinary schistosomiasis haematobium, VWF:ag and active VWF levels are elevated and do not correlate with platelet counts as thrombocytopenia is absent.

Changes in levels of VWF:ag and active VWF could reflect defects in the VWF-degrading protease ADAMTS-13 (Hulstein et al., 2005), but could also indicate endothelial activation (Lip & Blann, 1997). To study the functionality of ADAMTS-13, both ADAMTS-13:ag levels and ADAMTS-13 activity were determined. ADAMTS-13:ag levels and ADAMTS-13 activity were normal in both infected and non-infected children (P = 0.4116 and P = 0.5774, respectively; see fig. 1e, f), so no defects in VWF-degradation are present.

Next, endothelial activation was determined using OPG levels as a marker for inflammation-mediated endothelial activation (Zannettino et al., 2005). OPG is not directly involved in coagulation, as OPG is a cytokine of the TNF receptor superfamily involved in several physiological processes, among which are angiogenesis, osteogenesis and inflammation. Elevated levels of OPG were observed in the S. haematobium-infected children versus non-infected controls (P = 0.036; fig. 1g, dotted line indicates cut-off value). Simultaneous elevation of both VWF:ag and OPG during schistosomiasis haematobium indicates inflammation-mediated endothelial activation and is in line with the reported co-localization of these markers in endothelial Weibel Palade bodies and their simultaneous secretion upon endothelial cell stimulation (Zannettino et al., 2005).

Several mechanisms may explain activation of the vessel wall. Secretion of OPG is stimulated by the inflammatory cytokines TNF-α and IL-1β (Zannettino et al., 2005). In hepatosplenic schistosomiasis mansoni patients, TNF-α production by peripheral blood mononuclear cells (PBMC) is elevated and plasma levels of soluble TNF receptor I and II are increased (Mwatha et al., 1998), suggesting the contribution of inflammatory cytokines produced during infection to the observed increased OPG levels. However, no correlation between serum levels of TNF-α and infection status or disease severity is observed in schistosomiasis haematobium (Bustinduy et al., 2015). Passage of schistosome eggs through the vessel wall or egg-derived materials could also induce endothelial activation (File, 1995). Furthermore, endothelial adhesion of adult S. mansoni through their ventral sucker could damage the endothelium (Silva et al., 1998) and the presence of the adult worm pair in the small veins could alter blood flow, leading to endothelial activation (Mebius et al., 2013).

The observation that endothelial activation occurs during urinary schistosomiasis is of importance, as elevated levels of VWF, OPG and endothelial activation are associated with thrombosis and cardiovascular disease (Iono et al., 2002; Conway et al., 2003). Ongoing coagulation has been demonstrated in hepatosplenic schistosomiasis mansoni, reflected by increased levels of TAT and D-dimer (Tanabe, 2003). Therefore, we investigated whether the observed endothelial activation in urinary schistosomiasis haematobium results in a procoagulant phenotype in urinary schistosomiasis. In contrast to hepatosplenic schistosomiasis mansoni patients, TAT and D-dimer levels were generally low in our study population and we could not demonstrate differences in urinary schistosomiasis patients compared to the non-infected individuals (P = 0.4116 and P = 0.7524, respectively; fig. 2h, i, dotted line indicates cut-off value), indicating that there is no ongoing coagulation or fibrinolysis in these individuals.

However, five of the infected children had TAT levels above the normal threshold, without elevated D-dimer levels. Coagulation activation may have occurred in these individuals leading to low-level thrombin activation, followed by subsequent inhibition of the formed thrombin by antithrombin, leading to the formation of TAT without fibrin formation, which explains the absence of D-dimers in these individuals.

Here, we report the first study on the direct effects of S. haematobium on haemostatic abnormalities in urinary schistosomiasis. Interestingly, a VWF-cleaving peptidase was recently discovered in S. mansoni, which suggests that schistosomes have strategies to counteract endothelial activation and elevated levels of VWF, which are unfavourable for both the parasite and its host, as this can lead to thrombosis (Mebius et al., manuscript in preparation). Larger studies on endothelial activation in schistosomiasis haematobium patients with various disease severities are required to confirm our observations, and to elucidate the mechanisms involved in schistosomal-induced endothelial activation and the consequences of this endothelial activation on haemostasis.
