Abstract
Systematic reviews with economic components are important decision tools for stakeholders seeking to evaluate technologies, such as breast cancer screening (BCS) programs. This overview of systematic reviews explores the determinants of the cost-effectiveness of BCS and assesses the quality of secondary evidence. The search identified 30 systematic reviews that reported on the determinants of the cost-effectiveness of BCS, including the costs of breast cancer and BCS. While the quality of the reviews varied widely, only four out of 30 papers were considered to be of a high quality. We did not identify publication bias in the original evidence on the cost-effectiveness of mammography screening; however, we highlight a need for improved clarity in both reporting and data verification. The reviews consisted mainly of studies from high-income countries. Breast cancer costs varied widely among the studies. Factors leading to higher costs included: time (diagnosis and last months before death), later stage or metastases, recurrence of the disease, age below 64 years and type of follow-up (more intensive or more specialized). Overall, screening with...
mammography was considered cost-effective in the age range 50-69 years in Western European and Northern American countries but not for older or younger women. Its cost-effectiveness was questionable for low-income settings and Asia. Mammography screening was more cost-effective with biennial screening compared to annual screening and single reading using computer-aided detection vs double reading. No information on the cost-effectiveness of ultrasonography was found, and there is much uncertainty on the cost-effectiveness of CBE because of methodological limitations.

**KEYWORDS**
breast cancer screening, cost-effectiveness, costs, review

1 | INTRODUCTION

Systematic reviews are widely accepted as a tool to increase the flow of scientific information. A dramatic increase in primary health economic studies has led to a consequent proliferation of systematic reviews synthesizing this economic evidence. These reviews may serve as a decision tool for stakeholders by evaluating the methodological rigor of the available economic evidence, defining principal cost drivers, summarizing variability in economic outcomes, or identifying the scientific gaps requiring further exploration. As such, these summaries are especially useful for the prospective evaluation of large-scale programs requiring significant implementation and maintenance funding, such as breast cancer screening (BCS).

Breast cancer is the leading cause of death from cancer among women worldwide. Large randomized controlled trials and cohort studies, mainly conducted in North America and European countries, indicate that breast cancer mortality can be reduced by implementing screening mammography among women aged 50-59 years. While there are multiple discussions on the benefit to harm ratio of screening mammography, it is generally considered as favorable by most of the systematic reviews synthesizing outcomes from randomized clinical trials and observational or population studies. Thus, guidelines from international cancer networks—including the European Union Council Recommendation on Cancer Screening—recommend mammography screening for this segment of the population. Scarcity capacity limits application of these recommendations in low-income settings, where clinical breast examination (CBE), breast self-examination (BSE), and screening ultrasonography may be recommended by local guidelines either as individual or supplementary interventions.

To define if a screening program provides value for money, cost-effectiveness analysis is used. Cost-effectiveness analysis is a comparative method, which combines relative costs and outcomes of different interventions into a single metric—the cost-effectiveness ratio (CER) or incremental cost-effectiveness ratio (ICER). The most frequently used outcome measures in cost-effectiveness assessment of chronic illnesses, such as breast cancer, are quality-adjusted life years (QALYs, a measure of disease burden including the quality and duration of life) or disability-adjusted life years (DALYs, a measure of disease burden including the disability and years of life lost). Depending on the viewpoint of the stakeholders, cost-effectiveness analysis can consider a variety of costs, such as direct costs (costs of screening, treatment, follow-up, etc) and indirect costs (productivity loss for patient and caregiver). While multiple approaches to interpreting cost-effectiveness exist, new technologies, in general, are considered to have a favorable CER if it is lower than the threshold established in the country or if it is less than average per capita income per DALY.

The cost-effectiveness of BCS programs is dependent on economic and healthcare system settings as well as the methodological approaches toward evaluation. The factors that would affect the cost-effectiveness of BCS in populations would include patient characteristics and epidemiological factors, screening accuracy, coverage and screening uptake, access to diagnosis and treatment, and costs of both breast cancer and implementation of screening programs. While multiple reviews on economic evaluations around BCS have been published over the last decades, no research to our knowledge has summarized these reviews’ findings on the cost-effectiveness of the screening programs. In the current overview, we aim to explore determinants of the cost-effectiveness of BCS according to existing systematic reviews.

2 | METHODS

The design of this study was reported in the published protocol, available open-access online, and registered with the International Prospective Register of Systematic Reviews (PROSPERO), registration number CRD42016050765.
We systematically searched PubMed via Medline, Scopus, Embase, and Cochrane databases in August 2016 and conducted updates and searches for gray literature in April 2018 and again in August 2018 (Appendix 1). As a deviation from the protocol, we included two systematic reviews that conducted the search in only one country—the USA, since they presented the most comprehensive data on the costs of breast cancer.

The quality of the included reviews was assessed by using the Assessing the Methodological Quality of Systematic Reviews (AMSTAR) checklist relevant for systematic reviews of cost and cost-effectiveness outcomes and an additional question on transferability of the findings. We considered that the conclusions of the reviews were transferable to comparable jurisdictions, if the reviews reported low variability and uncertainty of the results, and considered the quality of original evidence as high or sufficient (Appendix 2 presents the decision framework). Furthermore, we narratively summarized the outcomes of the reviews that had a quality score of three or higher, considering the reviews with lower scores as nonsystematic. To explore the impact of the funding of the study, specialization of the department of the corresponding author, geographic focus of the review’s search, year of the search, and the outcomes reported (cost or cost-effectiveness), we used a stepwise multiple regression.

To analyze publication bias in the original evidence, we assessed the distribution of ICER per outcomes expressed in life years gained, QALYs, or DALYs in the reviews reporting on the cost-effectiveness of screening mammography comparing to no screening. Similar to Bell et al (2006), we considered that publication bias exists if the published ratios cluster around the countries’ decision thresholds. Countries’ acceptability thresholds were expressed from one to three times the gross domestic product (GDP) per capita in the year prior to the publication year of the original evidence.
3 | RESULTS

We identified 7768 abstracts through our database search, with 451 more gray literature sources reviewed (Figure 1). The interrater reliability between the two reviewers for decisions on full-text inclusion was 92% (Cohen’s kappa = 0.7; substantial agreement). The excluded reviews and reasons for the exclusion are outlined in Appendix 3.

Out of 30 included reviews, 14 reported data on the costs of breast cancer and 16 on the costs of BCS (the characteristics of the included studies are indicated in Appendix 4). Most reviews did not limit their search to a particular setting; some, however, aimed to identify studies comparable to either the UK,22,23 North America,24-29 Sweden,30 Iran,31 Asia,32 or high33- or low34-income countries. Most studies included in the reviews were conducted in high-income settings (Appendix 4), with little original research available for low- and middle-income countries. In particular, these reviews related to the cost-effectiveness of BCS in Brazil, India, Mexico, Turkey, Ghana, and Egypt and productivity loss in Brazil, Peru, and Pakistan. In total, only two included reviews reported low variability and uncertainty in the synthesized results; the results of these reviews were considered applicable to high-income countries.35,36 The results of the studies are presented according to the described framework (Figure 2), reporting first the breast cancer costs and then the cost and cost-effectiveness of BCS.

3.1 | The determinants of breast cancer costs

From a macroperspective point of view, almost half of breast cancer costs are related to medication costs, with nonmedical costs and productivity costs taking a quarter each.37,38 According to Foster et al,39 the financial impact of breast cancer (assessed on a macrolevel in the USA and Australia) was related to high trastuzumab costs and discard on its dispensed prescriptions. The results from the five reviews concluded that direct medical breast cancer costs on a microlevel increased in the initial year after diagnosis and the last months before death (for out-of-pocket costs—the last 12 months of life40), later stage or metastatic breast cancer patients, receiving adjuvant chemotherapy, recurrence of the disease than the initial cancer, and age younger than 64 years (vs an older age).37,39-41

Six reviews, mainly based on the same original evidence, reported resource use or costs of breast cancer follow-up (Appendix 5).22,30,35,42-44 The highest rate of resource use was for follow-up visits and follow-up mammography,44 while the frequency of visits decreased twice in the initial 4 years after...
treatment. The follow-up costs could be affected by poor continuity of the doctor-patient relationship, with patients seeing multiple doctors during the follow-up and doing almost twice the recommended number of visits. The cost of intensive follow-up was 2-5 times higher than minimal follow-up while not having an impact on survival; the cost of follow-up was lower if it was in the primary vs secondary setting, nurse-led, or nurse-led phone follow-up combined with an educational program, or phone or online application technologies. Even though no impact on clinical outcomes was recorded with follow-up in the primary setting, patients’ satisfaction was much higher with specialist follow-up.

Seven reviews concluded that breast cancer has a significant impact on the productivity of women in all the countries considered affecting the unemployment rate of breast cancer survivors and causing financial hardship for families of cancer patients. The unemployment rate varied widely among the studies and the countries (from 20%-55% at 3-24 months in Germany, the USA, and France to 12%-43% after 6-9 years in the USA, Sweden, Canada, and Germany). Because of heterogeneity in methods, background unemployment rates, and population characteristics, it is impossible to conclude on any real differences in the geographic settings. Similarly, the average return to work varied widely among the countries, for instance, being three times longer in the Netherlands than in Sweden.

3.2 Determinants of breast cancer screening costs and cost-effectiveness

Only one narrative review reported the costs of organized invitations, with the cost of follow-up reminder being 3-9 times higher than the cost of initial invitation. In general, mammography was considered to be cost-effective to screen 50- to 69-year-old women in three reviews reporting studies from Western European and North American countries, although questionable for low-income settings and Asian regions (that was argued by differences in incidence rates and density of breast tissues) (Table 1). BCS costs were lower with biennial mammography compared with annual mammography in the review of Health Quality Ontario (2016); consequently, biennial mammography screening was considered to be the most cost-effective option in the review by Rashidian et al (2013), although the range of cost per life year gained was the lowest for triennial screening. Incremental cost per life year gained of continuing mammography screening for women above 65 years of age compared with stopping regular screening at that age was $34000-$88000 USD (2002). Although it could possibly be lower if screening decision would be based on women’s health state. The cost-effectiveness of screening of women younger than 50 years of age had a range within the recommendations of the World Health Organization of three times GDP per capita ($14000-$26200 USD per life year gained in the USA in 1994 and $45000 USD per QALY gained in the UK, 2010). However, the authors of this systematic review did not consider BCS for this group of women cost-effective.

Several reviews assessed the impact of different organizational aspects on the cost-effectiveness of screening mammography. The review of Baron (2010) identified more than a 50% increase in cost of invitation for those women requiring a follow-up reminder to come for screening. The review by Ho et al (2002) identified significantly higher costs of capital equipment for digital mammography compared to film mammography, although the former reduced the number of examination repeats (1.5%-6%) and decreased examination time by around 5 minutes. Double reading was considered not to be a cost-effective intervention in comparison to single reading with computer-aided detection in the review of Posso et al (2017). Another review estimated the costs of personalizing screening intervals considering an individual’s cancer risk, concluding higher cost ($2000-$2500 USD, 2014) for a higher risk population.

While mammography was a target intervention in most of the reviews, three publications reported BCS costs for the other screening approaches (Table 1). Zelle et al (2013) reported that CBE can be a cost-effective screening method for some low-income settings (India, Ghana, and Egypt). Baxter et al (2001) estimated the range of costs ($574-$848 USD) necessary to educate one woman to regularly and competently practice breast self-examination. The report by Health Quality Ontario targeted to identify the cost-effectiveness of adjunct ultrasonography including women of general risk; no study for average risk women reporting the cost-effectiveness of combined screening was identified though.

3.3 Quality and bias in evidence on cost-effectiveness of breast cancer screening

The quality of the included reviews ranged from 1 to 7 (from a maximum possible of 9 in AMSTAR), of which 25 reviews had a quality score of three or above and were included in the data synthesis (Table 2). From the relevant AMSTAR criteria, most systematic reviews had a comprehensive literature search (81%) and reported study characteristics (84%). Only three reviews (10%) reported the conflict of interest for included original research, and only five (17%) reported having a protocol (Figure 3). A stepwise multiple regression model evaluated the impact of factors on the AMSTAR score. The final regression model excluded factors such as funding of the study and the specialization of the department of the corresponding author, including a geographic focus of the review’s search (world vs country or region-specific, $P < .05), year of the search ($P < .1), and reporting cost-effectiveness parameters vs only.

(Continues)
The model predicted 47% of variance in the AMSTAR score with residual standard error of 1.133 on 23 degrees of freedom.

Four systematic reviews on the cost-effectiveness of BCS in comparison to no screening reported the outcomes from 67 studies in total (Appendix 6). While most of the inclusion criteria were similar among the three reviews, 13%–60% of the original articles were not included in one or another review when expected. Among those studies included in two or more reviews, 10 out of 22 (45%) had different ranges for reported ICERs; these differences in the reporting were not related to a particular trend of cost-effectiveness estimates. Two of these four systematic reviews were used to assess the risk of publication bias. The other two were excluded due to poor reporting of programs and outcomes. We did not identify a risk of publication bias in the original studies with differences between GDP and ICER varying widely depending on the country of evaluation, screening interval, and age groups (Appendix 6).

### 4 | DISCUSSION

This systematic review assessed the determinants of the cost-effectiveness of BCS as well as the methods and quality of 30 included systematic reviews.

#### 4.1 | Determinants of the cost-effectiveness of mammography screening

The determinants of the cost-effectiveness of BCS were split into two stages indicated in the conceptual framework, the screening costs, and the breast cancer costs, with the later including the costs related to the diagnosis, treatment, and follow-up. Breast cancer costs were affected by the disease characteristics (eg, stage and incidence), patients’ characteristics (eg, age), health provider characteristics (eg, nurse vs general practitioner follow-up), and health system characteristics (eg, discard of dispensed prescriptions and lack of societal insurance). There was not enough evidence to evaluate how the impact of these factors on breast cancer cost would differ between high- and low-income countries. While low-income countries have less financial means and lower breast cancer expenses, wastage and improper resource allocation also contribute to the inefficiency of the healthcare systems in these jurisdictions.52 With high breast cancer mortality rates in countries with limited resources,52,53 one may speculate that improvement of the efficiency in healthcare systems, including cancer treatment in national health insurance coverage,54 gaining capacity, and setting early cancer detection programs,55 should go prior to BCS implementation.

The cost and cost-effectiveness outcomes related to screening were influenced by population characteristics (eg, age, personal cancer risk, and breast tissue density), screening organization (eg, screening interval, prompting, mammography type, and number of readers), and disease characteristics (eg, breast cancer incidence).27,31-33,47 Screening mammography was the most reported intervention in the reviews of the cost-effectiveness of BCS and was generally accepted as cost-effective for 50- to 69-year-old women in high-income settings but not in low-income settings or in Asian populations. What undervalues the economic assessments of BCS...

(Continues)
among younger and older women is that the evidence on the benefit/harm ratio of screening mammography in these populations is inconclusive or limited. Nevertheless, the conclusions on the cost-effectiveness of screening mammography among women younger than 50 years old or older than 69 years old could vary from those presented if other clinical outcomes were selected, since the incidence of breast cancer (and so advanced cases prevented) was higher among the older population (while the younger population accumulated more life years gained) or if the individual-based screening approach would be evaluated.

The results of this review have a dual-fold impact. Firstly, policy makers should take the factors listed above seriously, especially when new screening programs are designed. These factors are prerequisites for an optimal implementation of a cost-effective screening program, even though the BCS of 50- to 69 year-old women is considered to be, in general, a cost-effective intervention. A comprehensive cost-effectiveness evaluation of BCS with long-term forecasted outcomes supported by the evidence from local pilots would support efficient program design and functioning.

Secondly, the differences in healthcare systems, health providers, and populations as well as breast cancer costs and their determinants should be considered in estimations of the transferability of findings on the cost-effectiveness of BCS. The transferability approaches suggest that, at a minimum, practice patterns and unit costs from the jurisdiction of interest should be considered. In relation to prevention approaches,
not only the unit costs of the preventive intervention but also cost of the disease itself, would define transferability of cost-effectiveness estimates. Considering the long-term effect of the indirect costs related to breast cancer as well as high heterogeneity in cost outcomes by patient characteristics, an individual-level approach to model-based economic evaluations would be more relevant to capture the long-term impact of the disease on both the well-being and patient-related costs. Finally, the model parametrization approaches, in particular, calibration, will also affect the transferability of the cost-effectiveness results. Calibration is a strategy for quantifying unobserved model parameters to mimic the observed historical data. Considering that the natural history of the disease frequently includes undetected states and so transitions, calibration is frequently applied in health economic modeling approaches. The source of target data to fit in the calibration (whether it is a global, regional, or local source of statistics), would anchor the results narrowly (to one specific program or environment) or broadly (to multiple settings).

4.2 | Other breast cancer screening modalities

Besides mammography, limited (for BSE and CBE) to no (for ultrasonography) information was reported on other screening modalities. Even though CBE and BSE are generally perceived as low-investment approaches, they also require launch and maintenance costs related to the education and enrollment of women. Costs required for BSE education were reported in one review,26 and the cost-effectiveness of CBE in another review, suggesting it to be a cost-effective method for some low-income settings (India, Ghana, and Egypt).34 The secondary sources are consistent in presenting sufficient evidence of no benefits but harms of BSE and on insufficient evidence of a mortality decrease in breast cancer with regular CBE.3 By this, models assessing the benefits of CBE would rely on intermediary outcomes—stage shifting of breast cancer—rather than real-life data on mortality decrease, which underpins assessments of the cost-effectiveness of this intervention.

4.3 | Quality and bias in the evidence

While the quality of the reviews varied widely, only four of them were considered to be of a high quality (scored 6 or above on AMSTAR). Meanwhile, there was no clear relation between the quality of the included systematic reviews and their conclusions. Reviews having a wide geographic focus (world rather than targeting a certain country or region) and more recent search tend to have higher AMSTAR scores. Our more in-depth analysis of reporting from four systematic reviews has shown potential risk of search, selection, extraction, and reporting mistakes in the reviews rather than biases in these studies. Similarly, we did not identify publication biases in the original evidence. We consider that cost-effectiveness analyses of public preventive programs, such as BCS, may be at less risk of publication bias than pharmaceutical treatments. To improve the quality, reliability, and applicability of systematic reviews, the reviewers should refer to the developed guidelines in their methods, provide more transparent reporting of programs and outcomes, and consider the transferability of their findings.

4.4 | Research and information gaps

Our overview shows that more original trial-based economic evaluations along with pilots of CBE and ultrasonography with evidence on clinical and economic benefits are required. In addition, more high-quality field-based studies and reviews on the cost-effectiveness of mammography screening in low- and middle-income countries as well as the cost-effectiveness of mammography screening among older women are also required. Economic evaluations of BCS considering personal risk stratification would be an asset for health decision-making. A better understanding of costs related to informal care and indirect screening program costs would help to decide how these finances should be considered in economic analyses of breast cancer. Standard and better structured collection and reporting of costs would improve comparability among the studies. The risk of bias tool designed for the reviews reporting cost outcomes would help to interpret the results of these studies and potentially simplify their use in healthcare decision making.

4.5 | Limitation

With the large scope of the searched literature, it is possible that we missed some of the important information, despite the comprehensive approach applied in this review. We also deviated from the protocol, including two reviews on which agreement between two raters was not reached. The AMSTAR tool was not fully applicable to assess the quality of the systematic reviews with cost and cost-effectiveness outcomes. In addition, the applied transferability metric was not validated, and the use of a standard validated tool specific for systematic reviews of economic evaluations would be a preferable approach.

5 | CONCLUSIONS

Screening mammography may be a potentially cost-effective intervention, although how cost-effective it would depend on population characteristics (such as incidence and starting age for screening) and screening organization (screening interval and screening approach) as well as the direct and indirect costs of breast cancer and their determinants. No information on the determinants for the cost-effectiveness of ultrasonography was
retrieved, and the cost-effectiveness of CBE is not certain because of methodological limitations. No risk of publication bias in the original evidence was identified, although high variability and uncertainty in both the original and secondary evidence may limit the value of these reviews.
