Abstract

This paper examines international trade in tainted food and other low-quality products. We first find that for a large class of environments, free trade is the trading system that conveys the highest incentives to produce non-tainted high-quality goods by foreign exporters. However, free trade cannot prevent the export of tainted products, and the condition for tainting to arise becomes more easily satisfied, if the marginal cost of high-quality production increases or if errors of testing product quality matter. We also examine cases of image-building investments and sabotage of rivals, and find that a tariff in either case reduces the foreign firm's incentives to produce high quality, which in turn tends to increase import tainting.

1. Introduction

Media around the world abound with examples of malpractices in the daily running of international trade. In particular, headlines have alarmed consumers on the safety issues of imported products. Recently, it was revealed that some unscrupulous companies in China had routinely added melamine to milk to artificially boost protein readings in quality tests. Though imports from China have drawn the most criticism, producers in other developing nations violate basic food safety standards as well (Mexican cantaloupe, Indian relishes, etc.). Furthermore, firms of developed countries have also been known for committing the alleged crime of using dangerous ingredients. For example, Morinaga Milk Industry of Japan added industrial arsenic to improve the solubility of dairy products around 1953; aniline was added to rapeseed oil in Spain in 1981; and most recently, it was found that Peanut Corp. America continued to sell their tainted peanuts and pastes for more than a year, even after the company knew the products tested positive for salmonella. As more goods from distant locations are increasingly traded internationally, the question of what determines the deviant behavior of enterprises assumes considerable importance.

An important factor affecting firms’ behavior is consumers’ preference for domestically made products over imported goods, especially when it comes to buying food. Consumers in richer countries discount goods made abroad, more so those coming from developing countries such as China and India. Thus, goods with the same attributes become differentiated by their countries of origin, and are priced differently. Given this, various governments and consumer organizations of nations relying on food imports have repeatedly put forward the view that the process of further globalization should be halted. Central to the

1 Other cases include unapproved toothpaste, seafood containing antibiotics, deadly pet food, etc.
issue, is the popular conjecture that the global food crisis calls for more restrictions on international trade in order to increase consumption of local products.\(^2\)

This paper examines the theoretical premises of such conjecture in a model of quality choice, with international trade involving tainted food and other low-quality products. We are especially interested in the conditions where foreign firms have incentives to produce tainted goods. In addition, we ask questions such as: (i) Does globalization via freer trade lower product safety? (ii) How does a firm’s strategic behavior such as image building and sabotage affect rivals’ export quality? (iii) And ultimately how is consumer welfare affected?

Consider two firms Home (H) and Foreign (F) competing in the home market. The foreign firm has access to two technologies, one producing a low-quality variant (e.g., tainted food in the present model) and the other producing high quality. A domestic health authority that controls quality of imports is only able to inspect a small fraction of total shipments. This inspection ratio is determined by the home government and known to consumers before they make consumption decisions and to firms before they make their choices of output and investment in quality.\(^3\) Given this, our setup is a sequence of market structures that span over two periods. The foreign firm chooses the optimal quality strategy by maximizing the expected net present value of profits across qualities. Of these two technologies, which one is selected is private information of the foreign firm only.

The foreign producer has thus more information regarding the quality it sells and is fully aware that low-quality exports are tainted. In contrast home consumers are unable to

\(^2\) In Japan, a government survey conducted in September 2008 found that 89 percent of respondents said they would choose domestically produced products over imports; 93.2 percent said that Japan should be more self-reliant in procuring foodstuffs (The Daily Yomiuri, November 16, 2008).

\(^3\) For example, it is known that the US Food and Drug Administration checks only 1% of all shipments bound to the US market. In Japan, about 11% of imported goods are inspected (The Japan Times Online, Nov. 26, 2008).
recognize tainting before they actually purchase and use imported goods. This creates a problem of asymmetric information. Given this, we adopt the experience goods approach that allows consumers to learn about the product. The foreign firm’s quality becomes observable to consumers only through experience with the product, or by obtaining a certificate of quality issued by inspection authorities in the domestic country. Some consumers (usually with a lower income) are still willing to consume positive amounts of uninspected low-quality goods. Tainting takes them by surprise because the poisoning of goods is outside any prior regarding possible states of the world. Problems of asymmetric information in an international context have also been solved using quality-signaling games or signaling games of incomplete information. We believe that signaling is more appropriate when higher quality is involved. In the present paper, since we focus on lower quality and tainted goods, it is natural that sellers do not want to signal or be signaled as “tainted”. Sellers could signal quality in various ways, however, there is no guarantee that they do not over-report or even lie about quality. In addition, consumers from richer countries have usually a bias against foreign made goods, and thus experience seems more trustable than foreign promises or signaling. In fact, most cases of tainting and poisoning that are reported in the media were only discovered after incidents occurred, which supports the argument that consumption experience mattered more than other mechanisms.

---

4 In the literature, Nelson (1970) is the first to systematically analyze the differences between experience goods and search goods, and makes some predictions about consumer behavior and market structure with the two types of goods. Under experience goods, Chen (1991) shows that an R&D subsidy characterizes optimal infant industry intervention, and it can also help individual firms to appropriate the benefits of quality-enhancing investments. Bergès-Sennou and Watson (2005) focus on product labeling issues and show that for products purchased infrequently, introducing a reputable private label is unsustainable. However, more retailer bargaining power increases the likelihood of a private label good being marketed.

5 For papers on signaling quality of imports, see Bagwell and Staiger (1989), Qiu (1994), Shy (2000), and Daughety and Reinganum (2008) among others.

6 Numerous casualties were reported in a series of food incidents that occurred in the past several years. For example, six infants died and more than 300,000 became sick after consuming milk contaminated with melamine (International Herald Tribune, November 29, 2009).
We first find that for a large class of environments, free trade is the trading system that provides the highest incentives to produce non-tainted high-quality abroad. In the present model of experience goods, under an import tariff, the foreign firm’s profits are reduced for one period if it exports tainted goods (which cannot be sold in the second period), but for two periods if it produces high-quality goods. Under normal conditions profits are lowered more by the tariff with high-quality production than with tainted goods, which in turn reduces the foreign firm’s incentives to produce high-quality goods. However, free trade is neither a necessary nor a sufficient condition to exclude trade in tainted products.

The condition for tainting to arise is more easily satisfied if the marginal cost of high-quality production increases, and low quality is always produced if this marginal cost is sufficiently high. Likewise this condition is also more easily satisfied if errors of testing matter. The intuition can be roughly understood as follows. Some testing errors (the so-called Type I) harm the foreign exporter because its high-quality exports are prohibited after inspection. Other errors (the so-called Type II) are a tragedy from the domestic society’s standpoint, since inspectors mistake tainted goods for high-quality ones. Obviously the latter errors benefit the foreign exporter when he produces low-cost tainted goods.

The basic setup is then enlarged to cover cases where the foreign firm invests to enhance consumers’ perception of its products (i.e., image building). Then the result that free trade provides the highest incentives for high quality production is reinforced, the reasoning being that freer trade allows the foreign exporter to capture more rents from image building. Another interesting case is sabotage by domestic competitors, which arises more often when foreign imports are of high quality (low-quality imports will die in the second period and thus need not be sabotaged). We find that more tainting arises if an import tariff is imposed...
which would lower the domestic rival’s cost of sabotage and increase its sabotage activities. This in turn allows the domestic firm to strengthen its leadership in high-quality production and gain market power. Consumers on the other hand have the most to lose.

Our results are closely related to the observation that industrialized countries generally maintain relatively high tariff and nontariff barriers in agriculture and in processed food sectors. World Bank (2001) reports that average protection in those countries was about nine times higher for agriculture than for manufacturing imports. Though tariffs have decreased in recent years, nontraditional impediments such as health, technical and sanitary standards have replaced them, and compliance to these standards imposes additional costs on exporters from developing countries. Moreover, agricultural subsidies to member countries such as those in the EU and NAFTA countries worsen the situation. The present model implies that tainting is more severe in agriculture than in manufacturing imports; and an effective way of reducing tainting is to lower tariff and non-tariff barriers, contrary to the conventional wisdom that more import restrictions should be imposed. Obviously governments could try to increase inspection. However, due to type I and type II errors and especially the high cost of inspection (such as canned food or fresh produce), it often may not be feasible. Lowering trade barriers is perhaps necessary when in practice it is difficult to increase inspection due to various constraints related to budget, personnel, or technology.

Welfare analysis is complicated in this model because in the presence of tainting there is a difference between ex ante and ex post welfare, and how much welfare suffers ex post depends on how poisonous the tainted product is. However, the following point is clear: if tainting is not too poisonous, then importing some low-quality goods may yield higher welfare than importing only high-quality goods when the latter are too costly to produce.
The paper is organized as follows. Sections 2 and 3 lay out the setup of the model. Section 4 calculates expected profits across qualities and examines the conditions under which tainted food is imported. Sections 5 to 7 extend the model to include errors of testing, image-building investments and sabotage. Section 8 looks into domestic welfare and how it relates to model parameters. We conclude in Section 9.

2. The Basic Setup

Our framework consists of a domestic (H) and a foreign (F) producing firm that serve the domestic market only. Goods made in H have the highest recognition in both brand name and quality while those made in F have low acceptance by home consumers. There are two periods, 1 and 2. At the outset of period 1 firm F decides whether to produce and export low-quality or high-quality goods. In choosing quality, firm F anticipates the sequence of market structures of Table 1 and selects its quality based on the comparison of expected net present value of profits. Local health authorities inspect imports with exogenous probability $\mu$. Initially we assume that authorities can always tell if a good is non-tainted after inspection. Later in Section 5 we examine errors of testing, when inspection fails to uncover tainting.

Panel (a) of Table 1 describes the case when firm F decides to produce low quality. In the basic model we consider low quality to be synonymous with being tainted and poisonous, and relaxations will be discussed in detail in the conclusions. Given that firm F produces low-quality goods, if its exports are inspected, then the shipment is not allowed to enter; if not inspected then firm F’s exports are sold into the domestic market. As consumers cannot observe the quality of the imported good, they experience its quality instead by consuming the good in period 1 and then learn that it is of the low-quality type. With this experience they decide not to consume the low-quality good in period 2.
**Table 1** Firm F’s Strategies and Market Structures

(a) **Firm F Producing Low Quality**

<table>
<thead>
<tr>
<th>Inspection Probabilities</th>
<th>Period 1</th>
<th>Period 2</th>
</tr>
</thead>
<tbody>

<tr>
<td>No inspection (1−μ)</td>
<td>Duopoly with differentiated products</td>
<td>Duopoly with homogeneous products</td>
</tr>
</tbody>
</table>

Panel (b) of Table 1 describes the case of firm F producing high quality. If the product is inspected, it receives a certificate stating it is of the highest quality identical to homemade goods. Consumers do not need to experience the product to learn of its quality as the certificate is identifiable. For products that are not inspected, consumers learn of the quality through consumption and, in period 2 the qualities of all goods become known.7

Normally, higher quality goods require higher costs to produce. This, along with the market structure, will affect firm F’s profits. In panel (a) firm H is a monopolist in all cells except when goods are not inspected in period 1, when the market structure is a duopoly with differentiated goods since consumers differentiate goods by country of origin. In panel (b), the market structure is a duopoly with homogeneous goods in all cells except when goods are not inspected in period 1, in which case we have a duopoly with differentiated goods.

---

7 We abstract thus from cases where firm F may produce a mixture of low and high qualities to decrease the odds of detection. Also, with two qualities firm F may choose to produce high quality in period 1 and low quality in period 2. Experience leads then to misleading results in a finite time horizon, but not in an infinite horizon.
3. Consumer Demand

A typical Home consumer consumes a numeraire good $m$, and two differentiated goods $x$ and $x^*$, respectively produced by firm H and firm F. Goods made at Home have the highest quality while those made in F have low acceptance by home consumers, due to problems of reputation, asymmetric information, etc. Given the above, the typical Home consumer can be assumed to maximize the following utility function:

$$V(m, x, x^*) = m + U(x, x^*)$$  \hspace{1cm} (1)

where

$$U(x, x^*) = x + \theta x^* - (x^2 + x^{*2}) / 2 - \gamma xx^*$$  \hspace{1cm} (2)

where $\gamma \in (0,1]$ indicates the degree of substitutability between goods $x$ and $x^*$: the two goods become more substitutable as $\gamma$ increases.\(^8\) Similar demand specifications are used in the literature, see e.g. Dixit (1988) and Bester and Petrakis (1993).

Parameter $\theta \in [0,1]$ represents home consumers’ valuation of imports and bias against foreign production. With $\theta < 1$ the marginal utility that a home consumer derives from consuming the foreign good is lower than from home goods, reflecting the argument that consumers in rich countries discount imported goods from poor countries.\(^9\) In practice it can represent product quality, food safety or brand recognition, etc. As for the relationship between $\gamma$ and $\theta$, we can think of the former as coming from the manufacturing process, which causes the two products to be different possibly in appearance, quality, taste, etc. but the latter as coming from consumers’ perception of the products.

---

\(^8\) We do not consider the case where goods are complements, i.e., when $\gamma < 0$.

\(^9\) The marginal rate of substitution between units of the same commodity, produced in different countries, is different from unity when $\theta < 1$:

$$\frac{dx^*}{dx} = \frac{(1 - x - \gamma x^*)}{(\theta - x^* - \gamma x)}.$$
Denote by $p$ and $p^*$ the price for each firm’s product. Maximization of consumers’ problem in (1) subject to the standard budget constraint yields the inverse demand functions for goods $x$ and $x^*$ in units of good $m$:

$$p(x, x^*) = 1 - x - \gamma x^*, \quad p^*(x, x^*) = \theta - x^* - \gamma x$$ (3)

The corresponding direct demand functions are:

$$x(p, p^*) = \frac{1 - \theta \gamma}{1 - \gamma^2} - \frac{p}{1 - \gamma^2} + \gamma \frac{p^*}{1 - \gamma^2}, \quad x^*(p, p^*) = \frac{\theta - \gamma}{1 - \gamma^2} + \gamma \frac{p}{1 - \gamma^2} - \frac{p^*}{1 - \gamma^2}$$ (3’)

Equations in (3’) reproduce the properties known in the literature. For example, own-price effects are larger than cross-price effects. Also the market scale is higher for home goods than for foreign goods as long as $\theta < 1$.

4. Tainted Food

Since we focus on firm F’s choices and on home government’s design of incentives to improve import quality, let us assume that firm H always produces high quality using a production technology represented by the cost function $C(x) = cx$, with $c < 1$ to ensure positive demands. Home government levies a specific tariff $t$ on imports from F. Home health authorities charge a fixed fee $K^*$ to cover costs of inspection. The foreign firm has access to two technologies (indexed by $i$), one producing a low-quality variant $l$ and the other producing high quality $h$. Marginal costs are given by $c_i^*$ and $c_h^*$, and we require:

**Assumption 1**: $c_l^* \leq c_h^*$ and $c_h^* + t < c < 1$.

This assumption reflects technical requirements on quality control that drive up the cost of high quality relative to low-quality production. The marginal cost of tainted food production is assumed sufficiently low.
### 4.1 Market Structures

In equilibrium, different sets of prices will be charged depending on the quality choice made by firm F \((i=\text{l}, h)\). As most goods we are considering are processed goods for which capacity constraints play a lesser role, we assume firms in the product market compete in price\(^{10}\). Then, we can straightforwardly derive the equilibrium of the three market structures described in Table 1.

**Domestic Monopoly**

The domestic monopoly arises when local health authorities uncover tainted food. The situation arises also when consumers experience the imported commodity as tainted. Imports are then prohibited \((x_i^* = 0)\) and firm H becomes the sole supplier, as under autarky.

Given this information, domestic profits are \(\pi_i = (1-c)^2 / 4\) in all relevant periods and, the time profile of foreign profits becomes \(\pi_h^* = -K^*\) in the first period and zero otherwise.

**Duopoly with Homogenous Goods**

This is the case of three cells in Table 1 (b). When average costs are constant but not equal across firms, Bertrand competition yields an equilibrium in which the firm with the lowest marginal cost is the only one to produce positive output. The equilibrium price is then the limit price equal to (or slightly below) the marginal cost of the second most efficient firm:

\[
p_h = \max \{c, c_h^* + t\} = c
\]

It follows that domestic profits are driven down to zero and, foreign profits become:

\[
\pi_h^* = (1-c)(c-c_h^*-t)-K^*
\]

---

\(^{10}\) Results would not change qualitatively if Cournot competition is assumed instead but derivations would become more involving.
in period 1 and \( \pi^*_c = (1-c)(c-c^*_h-t) \) in other cells.

**Duopoly with Differentiated Goods**

A duopoly with differentiated goods arises in one cell of Table 1(a) and of Table 1(b), in period 1 and when imports are not inspected. Both firms make their supply decisions rationally. Each of them holds Bertrand conjecture about the decisions of the other producer. Profits of the two firms are respectively:

\[
\pi(p_t, p^*_t) = (p_t-c)x(p_t, p^*_t), \quad \pi^*_i(p, p^*_i) = \left[p^*_i - (c^*_i + t)\right]x(p, p^*_i), \quad i = l, h
\]

(6)

The Nash-Bertrand equilibrium can be obtained as:

\[
p_i = \frac{(2-\gamma^2 - \gamma\theta) + 2c + \gamma(c^*_i + t)}{(4-\gamma^2)}, \quad (7a)
\]

\[
p^*_i = \frac{\theta(2-\gamma^2) - \gamma + \gamma c + 2(c^*_i + t)}{(4-\gamma^2)}, \quad (7b)
\]

\[
x^*_i = \frac{(2-\gamma^2)(1-c) - \gamma(\theta - c^*_i - t)}{(4-\gamma^2)(1-\gamma^2)}, \quad (7c)
\]

\[
x^*_i = \frac{(2-\gamma^2)(\theta - c^*_i - t) - \gamma(1-c)}{(4-\gamma^2)(1-\gamma^2)}. \quad (7d)
\]

Using (7a) and (7c), the equilibrium profits of firm H are obtained as: \( \pi^*_i = (1-\gamma^2)x^*_i^2 \) for \( i = l, h \). Firm F’s equilibrium profits are obtained from (7b) and (7d):

\[
\pi^*_i = (1-\gamma^2)x^*_i^2, \quad i = l, h.
\]

(8)

The market equilibrium obtained in (7c) and (7d) has a number of properties. For example, there exists a prohibitive tariff \( \overline{\tau}_i = \left[\theta - c^*_i - \gamma(1-c)/ (2-\gamma^2)\right] \) that shuts down imports. Also \( x^*_i > x_i \) when \( c - c^*_i - t > 1 - \theta \), i.e., when the difference in marginal costs is less than offset by the difference in market scales. In addition, Assumption 1 implies \( x^*_i \geq x^*_h \) and from (8) it follows that \( \pi^*_i \geq \pi^*_h \), which makes this market equilibrium particularly interesting.
The above discussion is summarized in Table 2 in terms of foreign production and foreign profits. For the sake of clarity we introduce a first subscript to denote time, a second to represent quality as before, and superscript ‘I’ to indicate when imports are inspected.

### 4.2 Firm F’s Quality Choice

Firm F’s decisions are made at the outset of period 1, but affect the profits of two periods. Then the expected profits of low-quality production over two periods are given by:

\[
\Pi^*_l = \mu(\pi^*_l)' + \mu \delta (\pi^*_2)' + (1 - \mu)\pi^*_l + (1 - \mu)\delta \pi^*_2
\]

where \( \delta \) denotes the private discount factor across periods. Making use of Table 2(a):

\[
\Pi^*_l = -\mu K^* + (1 - \mu)(1 - \gamma^2)x^*_{1l}
\]  \( \text{(9)} \)

Parameter \( \delta \) plays no role in (9) as firm F is not active in the second period. On the other hand, expected profits of high-quality production over two periods:

\[
\Pi^*_h = \mu(\pi^*_1)' + \mu \delta (\pi^*_2)' + (1 - \mu)\pi^*_1 + (1 - \mu)\delta \pi^*_2
\]

Making use of Table 2(b) gives:

\[
\Pi^*_h = (\mu + \delta)\left[(1-c)(c - c^*_h - t)\right] - \mu K^* + (1 - \mu)(1 - \gamma^2)x^*_{1h}
\]  \( \text{(10)} \)

### Table 2 Foreign Firm’s Profits

(a) Low-quality

<table>

<td>((\pi^*_2)' = 0)</td>
</tr>
<tr>
<td>No inspection ( (1 - \mu) )</td>
<td>(x^<em>_l = \left(\frac{1}{4 - \gamma^2}\right)\left(\frac{1}{1 - \gamma^2}\right)\left((2 - \gamma^2)(\theta - c^</em>_l - t) - \gamma(1-c)\right))</td>
<td>(x^*_2 = 0)</td>
</tr>
<tr>
<td></td>
<td>(\pi^<em>_l = (1 - \gamma^2)x^</em>_{1l})</td>
<td>(\pi^*_2 = 0)</td>
</tr>
</tbody>
</table>
Therefore at the outset of period 1 firm F faces the following binary decision problem:

Max ($\Pi_i^*, \Pi_h^*$); that is, choosing the optimal quality strategy by maximizing the expected net present value of profits. Using (9) and (10) we can establish the following proposition:

**Proposition 1 (Tainted food):** Tainted food is produced and exported by the foreign firm when the following condition is fulfilled:

$$
\frac{(1-\mu)(2-\gamma^2)(c_h^* - c_i^*)}{(4-\gamma^2)(1-\gamma^2)} \left\{ (2\theta - c_h^* - c_i^* - 2t) - \frac{2\gamma(1-c)}{2-\gamma} \right\} > (\mu + \delta)(1-c)(c - c_h^* - t) \quad (11)
$$

**Proof:** The difference in expected profits between low- and high-quality productions is obtained by taking the difference between (9) and (10):

$$
\Pi_i^* - \Pi_h^* = -(\mu + \delta)[(1-c)(c - c_h^* - t)] + (1-\mu)(1-\gamma^2)(x_{ih}^{*2} - x_{ih}^{-2}) \quad (12)
$$

Making use of (7d) to substitute for $x_{ij}$ and $x_{ih}^*$:

$$
\Pi_i^* - \Pi_h^* = -(\mu + \delta)[(1-c)(c - c_h^* - t)] + \frac{(1-\mu)(2-\gamma^2)^2(c_h^* - c_i^*)}{(1-\gamma^2)(4-\gamma^2)^2} \left\{ (2\theta - c_h^* - c_i^* - 2t) - \frac{2\gamma}{2-\gamma}(1-c) \right\} \quad (12')
$$

which is positive when condition (11) is met. ■
Firm F chooses to export tainted products when condition (11) is met, that is when single-period profits of low-quality production are higher than multi-period profits of high-quality production. As formulated in (11), the first term represents the positive difference between profits of low- and high-quality production when home and foreign products are differentiated. The second term represents profits from high-quality production under limit pricing. As condition (11) depends on all primitive parameters of the model, namely the marginal costs, parameters $\gamma, \theta, \delta, \mu$, and the import tariff $t$, Table 3 reproduces its monotonicity results, from which we obtain:

**Proposition 2:** The incentives to produce tainted products are decreased if the inspection rate $\mu$, the discount factor $\delta$ or the cost of producing low-quality $c^*_l$ rises. On the other hand, an increase in the foreign firm’s scale parameter $\theta$ or the marginal cost of home production $c$ raises the foreign firm’s incentives to produce tainted products.

**Proof:** see Table 3.

**Table 3 Monotonicity Results of Equation (11)**

<table>
<thead>

<td>?</td>
<td>-</td>
<td>+</td>
<td>+</td>
<td>?</td>
</tr>
</tbody>
</table>

Note that expression (11) is never met and tainted products are never produced when $c^*_h = c^*_l$. The intuition is that high-quality production is never out of reach for firms in the foreign country, simply because compliance costs that must be incurred to meet the sanitary standards imposed by the H government are low. These producers prefer then to make and
export high-quality products. However, increasing $c_h^*$ has a non-linear effect on the profit differential but the sign cannot be determined \textit{a priori} (though expected to be positive).

In Table 3, free trade is represented by setting $t = 0$. From (11) the inequality sign does not necessarily reverse with $t = 0$, that is, free trade alone cannot exclude trade in tainted products. However, firm F’s incentives can be compared under free trade and under a positive tariff. To that end we focus on $(\Pi_h^* - \Pi_t^*)$ instead, and making use of (12’) gives:

$$\frac{\partial(\Pi_h^* - \Pi_t^*)}{\partial t} = -\frac{\partial(\Pi_t^* - \Pi_h^*)}{\partial t} = -(\mu + \delta)(1-c) + \frac{2(1-\mu)(2-\gamma^2)^2}{(1-\gamma^2)(4-\gamma^2)^2}(c_h^* - c_i^*) \quad (13)$$

Expression (13) can be either positive or negative. The first term represents the loss in profits from high quality when limit pricing is applied whereas the second term measures the net gain in profits under product differentiation. We thus have the following result, noting that freer trade in our framework means a decrease in $t$:

\textbf{Proposition 3 (Free trade):} Free trade is the trading system that gives the highest incentives to foreign exporters to produce non-tainted high-quality goods when:

$$(\mu + \delta)(1-c) > \frac{2(1-\mu)(2-\gamma^2)^2}{(1-\gamma^2)(4-\gamma^2)^2}(c_h^* - c_i^*). \quad (14)$$

However, free trade is neither necessary nor sufficient to exclude trade in tainted products.

Condition (14) describes the parameter space under which free trade is the optimal trading system. It is fulfilled when $c_h^* = c_i^*$ but may fail to hold with $c_h^* \gg c_i^*$. This shows that the free trading system can be undermined by national governments which in practice introduce nontraditional impediments such as health, technical and sanitary standards whose compliance imposes additional costs on exporters from developing countries.
Figure 1 gives a graphical representation of (14) for \( c_i^* \) given. Values for \( c \) and \( c_h^* \) are allowed to vary between 0 and 1 but are constrained by the two inequalities of Assumption 1, depicted here by lines \( c_h^* < (c-t) \) and \( c < 1 \). The downward sloping line is the solution of \( c_h^* \) in terms of \( c \) such that condition (14) is satisfied. Every combination below this line indicates when the inequality sign holds strictly. The shaded area gives all combinations of \( c_h^* \) and \( c \) where free trade is the policy of choice that excludes tainting. That free trade can be optimal runs counter to the popular claim put forward by some government officials and consumer organizations that favor increased protectionism as a means to prevent tainted imports.

**Figure 1 Tainting and Free Trade**

Notes: (a) The shaded area gives all pairs \((c_h^*, c)\) such that free trade is optimal; (b) \( \Omega_i = (\mu + \delta)(1-\gamma^2)(4-\gamma^2) / 2(1-\mu)(2-\gamma^2) > 0 \).

5. **Type I and Type II Errors of Testing**

So far we have assumed that inspection is perfect so that all low-quality, tainted goods are found and banned from entering country H. However, as plenty of evidence
shows, errors of testing arise frequently when inspectors fail to find fault with tainted goods, and by mistake, label them as high-quality goods. We investigate this situation here.

Let us assume that the null hypothesis (H$_0$) is the presumption of innocence, meaning the absence of tainting in foreign exports. Given this, Table 4 describes the two possible errors that are made in testing procedures. A Type I error ($\alpha$) is highly undesirable from the foreign exporter’s standpoint: with probability $\alpha$, its high-quality good is by mistake found of being tainted. Then his exports are denied entry into the domestic market and his reputation is tarnished. A Type II error ($\beta$) is a tragedy from the domestic society’s standpoint: with probability $\beta$, foreign tainted goods are by mistake not detected. As a consequence, a certificate of high quality is issued and consumers’ health is in jeopardy.

<table>
<thead>
<tr>
<th></th>

<td>Correct</td>
<td>Type II error ($\beta$):</td>
</tr>
<tr>
<td></td>
<td></td>
<td>false negative</td>
</tr>
</tbody>
</table>

Errors of testing affect the likelihood of different market outcomes but only occur when inspection is first performed. Table 5 reproduces part of Table 2 but corrects inspection probabilities for testing errors. Under Type I error $\alpha$, high-quality products are considered as tainted and excluded from the market, leading to new entries in panel (b) of Table 5:

11 The New York Times (March 6, 2009) cites many examples in “Food Safety Problems Elude Private Inspectors”. For instance, the American Institute of Baking which after performing audits at Peanut Corp. America, reported that “the overall food safety level of this facility was considered to be superior.” Federal investigators later discovered salmonella.
\((x_{1h}^*)' = 0, \quad (\pi_{1h}^*)' = -K^*, \quad (x_{2h}^*)' = 0, \quad (\pi_{2h}^*)' = 0.\)

Expected profits of high-quality production can be computed as:

\[
\Pi_h^* = (\mu + \delta - \mu\alpha(1 + \delta))[\gamma(1-c)(c - c_h^* - t) - \mu K^* + (1 - \mu)(1 - \gamma^2)x_{1h}^*].
\]

(15)

Compared to (10) a new negative term linked to Type I error \(\alpha\) enters (15). A Type I error harms the foreign exporter because its exports that were previously sold at the high-quality price are now prohibited after inspection. The beneficiary of the Type I error is the domestic firm since with probability \(\alpha\) it becomes a monopolist in all periods.

**Table 5 Testing Errors and Foreign Firm’s Profits**

<td>((\pi_{2h}^*)' = 0)</td>
</tr>
</tbody>
</table>

The effect of a Type II error is more consequential. It follows that in period 1 low-quality foreign imports are labeled as high-quality and compete with homemade goods so we have a homogenous duopoly where the limit pricing rule applies. However, in period 2,
consumers having experienced tainted imports refuse to buy them anymore, and the domestic firm becomes a monopolist. We thus have the following entries in panel (a) of Table 5:

\[
(x_{i_t}^*)' = 1 - c, \quad (\pi_{i_t}^*)' = (1 - c)(c - c_i^* - t) - K^*, \quad (x_{i_t}^*)' = 0, \quad (\pi_{i_t}^*)' = 0.
\]

As indicated earlier, firm F’s decisions are made at the outset of period 1, but affect the profits of two periods. Repeating the steps of the preceding section, expected profits under low-quality production can be computed on the basis of Tables 2 and 5:

\[
\Pi_i^* = -\mu K^* + \mu \beta (1 - c)(c - c_i^* - t) + (1 - \mu)(1 - \gamma^2)x_{i_t}^*.
\] (16)

Compared to (9), a new term that reflects Type II error enters positively in (16): a Type II error benefits the foreign exporter when he produces low-cost tainted food because with probability \(\beta\) its tainted goods are now allowed to sell at the high-quality price. With \(\alpha = \beta = 0\), (15) and (16) reduce to (10) and (9) respectively, and using them, the difference in expected profits between low- and high-quality productions becomes:

\[
\Pi_h^* - \Pi_l^* = -(\mu + \delta - \mu \alpha(1 + \delta))[1 - c(c - c_h^* - t)] + \mu \beta [1 - c(c - c_i^* - t)]
\]

\[
+ \frac{(1 - \mu)(2 - \gamma^2)^2}{(1 - \gamma^2)(4 - \gamma^2)^2} (c_h^* - c_i^*) \left\{ 2\theta - c_h^* - c_i^* - 2t - \frac{2\gamma}{2 - \gamma}(1 - c) \right\}.
\] (17)

From (17) and the above discussion we can establish the following proposition:

**Proposition 4 (Type I & Type II errors):** Type I errors (\(\alpha\)) and Type II errors (\(\beta\)) of testing increase profits and incentives to produce and export tainted products.

From (17), testing errors also change how the tariff affects the profit differential:

\[
\frac{\partial (\Pi_h^* - \Pi_l^*)}{\partial t} = -[\mu + \delta - \mu \alpha(1 + \delta) - \mu \beta](1 - c) + \frac{2(1 - \mu)(2 - \gamma^2)^2}{(1 - \gamma^2)(4 - \gamma^2)^2} (c_h^* - c_i^*)
\] (18)
which reduces to (13) when $\alpha = \beta = 0$ but is larger otherwise. Depending on the values of $\alpha$ and $\beta$, (18) can turn negative. As a result the shaded area that gives all combinations of $c_h^*$ and $c$ such that free trade is the prevailing policy is smaller in Figure 2 than in Figure 1. Thus, testing errors undermine the free trading system as a devise to provide incentives to produce and trade high-quality products.

**Figure 2  Testing Errors and Free Trade**

![Graph showing testing errors and free trade](image)

*Notes:* (a) The shaded area gives all pairs $(c_h^*, c)$ such that free trade is optimal;

(b) $\Omega_2 = \mu(1 - \alpha(1 + \delta) - \beta) + \delta(1 - \gamma)(4 - \gamma') / 2(1 - \mu)(2 - \gamma') > 0$ with $\Omega_2 < \Omega_1$.

**6. The Role of Investments**

So far $\theta \leq 1$ has been assumed exogenous. However, foreign firms can undertake investments to enhance consumers’ perception of their products. The objective is to affect consumers’ preference which usually favors homemade goods over imports, especially when they come from developing countries or when it concerns food products. Investments could
be done via advertising campaigns and trade fairs. Hence, $\theta$ becomes endogenous and an ‘optimal’ $\theta$ can be obtained in our model by introducing profit-maximizing investments.\textsuperscript{12}

Firm H that enjoys the reputation of a high-quality producer may counteract firm F’s attempt by damaging the latter’s product image. The market would evolve then in two stages, with both firms deciding simultaneously on how much to invest. However if $c - c^* - t > 1 - \theta$, foreign imports are higher than home production ($x^*_l > x_l$) since the marginal-cost difference is less than the market-scale difference. Also $(1 - \gamma^2)x^*_l > (1 - \gamma^2)x^*_l$; that is, the operational profits are higher for F than for H, enabling F to outcompete H in an investment game if the latter decides to lower F’s product image. Hence, H which has other more rewarding disrupting activities (see next section) does not participate, and F becomes the sole investor.

A duopoly with differentiated goods arises in one cell of Table 1(a) and 1(b), in period 1 and when imports are not inspected. With investment the market is assumed to evolve in two stages, decisions made in stage 1 being fully observable in stage 2. First, firm F decides unilaterally on how much to invest in perception enhancement. Second, both firms make their supply decisions rationally. We assume Bertrand conjecture and solve the model by backward induction as before.

As the solution obtained in (7a)-(7b) and (8) describes the market equilibrium of the second stage it suffices to focus on the investment decision in the first stage. Profits of the two firms in the second stage of the game are respectively:

$$\pi_i = (1 - \gamma^2)x^*_i, \quad \pi^*_i = (1 - \gamma^2)x^*_{i} - f^*, \quad i = l, h$$

\textsuperscript{12} There are however some constraints. For example, investments are only optimal under differentiated products since in other market structures, imports are either prohibited or experienced and certified, which make investments redundant.
where \( f^* \) denotes first-stage investment which is common to both qualities and where outputs \( x_i \) and \( x_h \) are given by (7c) and (7d). In the first stage, firm F tries to improve home consumers’ perception of its product. In particular, it invests in order to increase its market scale variable \( \theta \) by using the following linear technology:

\[
\theta = \omega + \lambda f^*
\]

As firm F does not want to reveal its product quality, it chooses a single level of investment across product qualities. We assume it does so by maximizing the sum of first-period profits \( (\pi_l^* + \pi_h^*) \). Using (20) in \( x_i^* \), profit maximization with respect to \( f^* \) gives:

\[
\frac{\lambda(2-\gamma^2)}{(4-\gamma^2)}(x_i^* + x_h^*) = 1
\]

Together with (7c) and (7d), this first order condition yields:

\[
\begin{align*}
\theta &= \frac{(4-\gamma^2)^2(1-\gamma^2)\lambda}{2(2-\gamma^2)^2} + \frac{\gamma(1-c)}{(2-\gamma^2)} + \frac{(c_i^* + c_h^*)}{2} + t, \\
\frac{f^*}{\theta} &= \frac{\omega - \omega}{\lambda}.
\end{align*}
\]

The optimal level of investment is chosen such that outputs across qualities satisfy also:

\[
(\gamma_i^* - \gamma_h^*) = \frac{(2-\gamma^2)}{(4-\gamma^2)(1-\gamma^2)}(c_i^* - c_h^*),
\]

\[
\pi_i^* - \pi_h^* = (1-\gamma^2)x_i^* - f^* - (1-\gamma^2)x_h^* + f^* = \frac{(c_h^* - c_i^*)}{\lambda}.
\]

Given this information firm F’s quality choice is readily obtained. Repeating the steps of Section 4 expected profits of low-quality production can be obtained as:

\[
\Pi_l^* = -\mu K^* + (1-\mu)(1-\gamma^2)x_i^* - (1-\mu)f^*
\]

On the other hand, expected profits of high-quality production are:
\[ \Pi_h^* = (\mu + \delta)[(1-c)(c-c_h^*-t)] - \mu K^* + (1-\mu)(1-\gamma^2)x_i^2 - (1-\mu)f_i^* \]

Making use of (23), the difference in expected profits between high- and low-quality productions becomes:

\[ \Pi_l^* - \Pi_h^* = -(\mu + \delta)[(1-c)(c-c_h^*-t)] + \frac{(1-\mu)}{\lambda}(c^*_h - c^*_l) \]  \hspace{1cm} (24)

Using (24) we can establish the following proposition:

**Proposition 5 (Investment & tainted food):** The foreign firm will produce and export tainted food when it is optimal to invest resources in image building under the condition:

\[ \frac{(1-\mu)}{\lambda}(c^*_h - c^*_l) > (\mu + \delta)(1-c)(c-c_h^*-t), \]  \hspace{1cm} (25)

The incentives to produce low quality in (25) can be compared with those in (11). The former is satisfied when \( c^*_h \gg c^*_l \). The intuition is that high-quality production is out of reach for some firms in the foreign country, due to, say, too high compliance costs that must be incurred to meet the high sanitary standards imposed by the H government. Those firms then decide to skimp on quality and export tainted products. This is possible as long as local health authorities are only able to check a very small fraction of total shipments.

Another implication of this scenario is the clear cut effect of the specific tariff \( t \):

\[ \frac{\partial(\Pi_h^* - \Pi_l^*)}{\partial t} = -\frac{\partial(\Pi_l^* - \Pi_h^*)}{\partial t} = -(\mu + \delta)(1-c) < 0 \]  \hspace{1cm} (26)

Unambiguously, an increase in \( t \) causes, *ceteris paribus*, a decrease (increase) in the incentives to produce high-quality goods (tainted products). As a result the shaded area of
Figure 3 that gives all parameter combinations that support free trade is enlarged and includes all feasible parameter combinations. We thus have:

**Proposition 6 (Investment & free trade):** When the foreign firm invest resources to improve consumers’ perception of its product, free trade is the trading system that provides the highest incentives to foreign exporters to produce non-tainted high-quality goods.

Again, this result runs counter to the popular claim by some government officials and consumer organizations that favor increased protectionism as a means to prevent tainted imports. Together with Proposition 3, it shows freer trade is necessary to induce high-quality non-tainted imports, when governments in practice cannot raise the rate of import inspection.

![Figure 3 Investment and Free Trade](image)

*Note:* The shaded area gives all pairs \((c^*_a, c)\) such that free trade is optimal.

7. Sabotage

Foreign firm’s export success is very often subject to countermeasures by the domestic firm which does not want the market for its products to fade away. Possible reactions are sabotage activities by domestic competitors. The term ‘sabotage’ usually refers
to countermeasures in market contests that are almost unobservable and sometimes illegal. The idea that stems from Veblen (1923) in the context of business competition and market power has since been considered in several fields: for example, Baumol (1992) on innovation, Salop and Scheffman (1987) and Roy and Viaene (1998) on raising rivals’ cost, Lazear (1989) on contests within firms and Konrad (2000) on lobbying efforts for policy favors. Sabotage activities take at least two forms. One is damaging the rival’s image, and the other is increasing the rival’s costs. Since we have shown in the preceding section that the former is dominated by firm F’s image-building investments, we shall focus on the latter.\(^\text{13}\)

Raising rival’s cost is effective for firm H, simply because some of the market equilibria of Table 1(b) might reverse in its favor. Denoting sabotage activities by \(s\), marginal costs can be expressed as \(c^*_{ij}(s)\) with \(\partial c^*_{ij}(s)/\partial s > 0\). We obtain straightforwardly:

**Proposition 7 (Sabotage):** Sabotage by the domestic firm aimed at raising the foreign firm’s marginal cost of production: (i) decreases the likelihood of tainting if the marginal cost of low quality is increased; (ii) causes tainting if the marginal cost of high quality is increased.

**Proof:** Sabotage of low-quality production affects only one cell of Table 2(a): when the imported good is not checked, for which consumers have to gain experience. In this case only (12) is affected. With \(c^*_{ij}(s)\) increasing in \(s\), sabotage reduces both \(x^*_{ij}\) and the right hand side of (12). The likelihood of tainting decreases which proves part (i). To prove part (ii) note that sabotage of high-quality production affects all market equilibria of Table 2(b). With sufficient sabotage activity, the limit pricing condition (4) reverses to:

---

\(^{13}\) Examples include business interruptions caused by strikes, punctured packaged products, sabotage in counterfeit hardware, sabotage of networks, etc. Bailed out American International Group advertises insurances that are designed to cover these specific risks (see the AIG Web site).
\[ p_n = \max \{c, c_n^*(s) + t\} = c_n^*(s) + t \]  \hspace{1cm} (4')

Foreign profits in Table 2(b) then become:

\[(\pi_{1h}^*)' = -K^*, \quad (\pi_{2h}^*)' = \pi_{2h}^* = 0\]

In turn, domestic profits take the following values:

\[(\pi_{1h}^*)' = (\pi_{2h}^*)' = \pi_{2h}^* = \left[1 - (c_n^*(s) + t)\right]c_n^*(s) + t - c \]  \hspace{1cm} (5')

Using (5'), the participation constraint of the domestic firm in sabotage activities is:

\[(\mu + \delta)\left[1 - (c_n^*(s) + t)\right]c_n^*(s) + t - c > s\]

Turning now to expected profits, while (9) remains unchanged, (10) becomes:

\[\Pi_h^* = -\mu K^* + (1 - \mu)(1 - \gamma^2)x_{1h}^{*2} \]  \hspace{1cm} (10')

The difference in expected discounted profits between low- and high-quality productions is obtained by taking the difference between (9) and (10'):

\[\Pi_l^* - \Pi_h^* = (1 - \mu)(1 - \gamma^2)(x_{1l}^{*2} - x_{1h}^{*2}) > 0\]

that is always positive. Thus tainting in this case is caused by sabotage of high-quality production by the domestic firm.

This proposition has important implications. First note that sabotage of low-quality tainted imports affects profits in the first period when imports are not checked whereas sabotage of high quality affects multi-period profits under all inspection status. The dominant strategy of firm H is therefore to affect firm F’s marginal cost of high quality. Firm F taking this into account will produce the low-quality variant, even worse, the incentives to produce tainted goods increase. This will allow the domestic firm to enjoy a monopoly position as
described in Table 1. Home consumers have the most to lose as a consequence, since sabotage increases both foreign tainting and the home firm’s market power.

In addition, we can characterize the cost-minimizing level of sabotage activity. Let \( \overline{s} \) denote the level of sabotage such that average costs are just equal across firms. Any sabotage activity slightly above \( \overline{s} \) allows the domestic firm to be more efficient. From the limit price condition (4) we have: 

\[
p_h = c = c_h^*(\overline{s}) + t.
\]

Solving for \( \overline{s} \) gives 

\[
\overline{s} = c_h^{*^{-1}}(c-t) \quad \text{with} \quad \frac{\partial \overline{s}}{\partial t} < 0.
\]

Hence we straightforwardly obtain the following result:

**Proposition 8 (Sabotage & Free trade):** Free trade increases the domestic firm’s cost to sabotage foreign production of high quality, which consequently lowers tainting.

**8. Welfare**

Whatever the choice of firm F, aggregate welfare of the home country is important. The H government can increase inspection \( \mu \) by spending more resources, and/or use tariffs to maximize welfare across firm F’s choices. However, the measurement of welfare is a complex issue with experience goods. The *ex ante* consumer surplus derived from consumption choices differs from unknown *ex post* consumer surplus because the latter includes the disutility generated by first-period consumption of eventually tainted goods. If consumption of tainted food leads to diseases or death, the disutility is so overwhelming that the aggregate welfare may become negative. On the other hand, more often less extreme situations exist. Defective products for example do not put public health in danger and their consumption is justified if prices are sufficiently low. Also the tariff has two opposing effects. It raises both the consumer price and the tariff revenue. Thus the source of gain for the H government resides in the optimal capture of the foreign exporter’s surplus.
Domestic welfare is defined as the arithmetic sum of consumer surplus ($CS_i$), home firm’s profits ($\pi_i$) and tariff revenue ($R_i$): $W_i = CS_i + \pi_i + R_i$. Using consumers’ utility in (1) and (2), consumer surplus can be written as the net utility derived from consuming $x_i$ and $x_i^*$:

$$CS_i = (1 - p_i)x_i + (\theta - p_i^*)x_i^* - (x_i^2 + x_i^{*2}) / 2 - \gamma x_i x_i^* , \; i = l, h$$

(27)

Thus an increase in prices reduces the consumption of the numeraire good and utility.

</tbody>
</table>
Table 6 reproduces the components of welfare across periods and inspection status. The cells are obtained using preceding derivations, and we emphasize that the *ex ante* measure of consumer surplus is used. The expected utility under quality $i$ is given by:

$$\psi_i = \mu(W_{i1})^t + \mu\delta(W_{i2})^t + (1-\mu)W_{ih} + (1-\mu)\delta W_{i2}, \quad i = l, h$$

where $\delta$ denotes the private discount factor common to all agents. Using Table 6 yields:

$$\psi_l = 3(\mu + \delta)(1-c)^2 / 8 + (1-\mu)\left[CS_{il} + (1-\gamma^2)x_{il}^2 + tx_{il}^2\right], \quad (28a)$$

$$\psi_h = (\mu + \delta)\left[(1-c)^2 / 2 + t(1-c)\right] + (1-\mu)\left[CS_{ih} + (1-\gamma^2)x_{ih}^2 + tx_{ih}^2\right], \quad (28b)$$

which gives the expected present value of welfare difference between high- and low-quality:

$$\psi_h - \psi_l = (\mu + \delta)(1-c)\left[(1-c)/8 + t\right]$$

$$+ (1-\mu)\left[CS_{ih} - CS_{il} + (1-\gamma^2)(x_{ih}^2 - x_{il}^2) + t(x_{ih}^2 - x_{il}^2)\right]$$

(29)

The first term is positive, since the market for high-quality products is more competitive. The contribution of the second term is unknown under general conditions because the difference in consumer surpluses cannot be signed analytically.\(^{14}\)

Given this, we perform numerical simulations to give an interpretation to (29). Figure 4 reproduces these in a three-dimensional graph combining $t$, $c$ and $c^*_h$, based on a grid between 0 and 1 and parameter drawings are constrained by Assumption 1. The graph illustrates the difference in present-value welfare between high- and low-quality production, that is the threshold $\psi_h - \psi_l = 0$. The area below or to the right of the plane is indicative of a welfare of low quality that exceeds that of high quality ((29) is negative); *vice versa* for the

---

\(^{14}\) When optimal, investments in image building connect $\theta^i$'s across quality types. This eases the comparison of consumer surpluses, and thus the analytical difficulty disappears.
area to the left of the planes. An important conclusion to draw from Figure 4 is that the set of parameters under which low quality is preferred to high quality is not empty. A higher $\theta$ would increase ceteris paribus the area under this plane. Likewise the area under the plane (see (29)) becomes larger when $\mu$ or $\delta$ decreases.

*Note: Assumed parameter values: $\mu = 0.11$; $\delta = 1/(1.05)$; $\gamma = 0.5$; $c^* = 0$; $\theta = 0.7$*

9. **Concluding Remarks**

This paper considered international trade in tainted food and examined various designs of incentive schemes for exporting firms to produce non-tainted, high-quality products. The issue arises because many governments and consumer organizations relying on food imports have repeatedly put forward the view that the process of further globalization should be halted. Central to the issue, is the popular conjecture that the global food crisis calls for more restrictions on international trade in order to prevent imports of tainted food. However, a main result of this paper shows the opposite: for a large class of environments, free trade is the trading system that provides the highest incentives to foreign exporters to
produce non-tainted high-quality goods. This is reinforced when the foreign firm undertakes image building investments. Moreover, imposing a tariff may decrease the cost of sabotage activities by the domestic firm, further increasing the foreign firm’s incentives to produce low quality and raising the domestic firm’s market power. As a consequence, home consumers lose as they pay higher prices due to more market concentration.

The setup of this paper could be extended in a number of ways. For example, so far we have assumed that a low-quality good is not imported once inspected by authorities. It is possible to allow imports of such goods as long as they are not poisonous. The model becomes then a model with two different types of qualities (but not tainting). The assumption of certification could also be relaxed. With certification, there is no reason for consumers to discount imports. Authorities certify that foreign goods are of the same grade as home goods. This was the scenario envisaged in Table 1(b). However, an inefficient firm H has incentives to lobby the government against the act of certification simply because in its absence, consumers keep on discounting foreign goods and product differentiation is maintained. Most qualitative results of the paper are not altered in this new setting. In addition, many industrial countries rely on imports for most of their food products. Hence, relying on a single home producer as indicated in Table 1 might not be feasible once tainted food is uncovered (by inspection or by experience), simply because the home monopolist does not produce enough in calorie terms. Finding a substitute for firm F is possible if the model considers more foreign firms. This would not change results as long as Assumption 1 is maintained, i.e., as long as the firm with the lowest marginal cost is an exporting firm. Bertrand competition then

\[15\] For example, Japan’s food self-sufficiency rate stood at 39 percent in 2006, the lowest level in industrialized countries. Rice, eggs and a few other types of food are the only food items the country currently produces sufficiently to meet domestic demand (The Daily Yomiuri, November 4, 2008).
yields market equilibria that are similar to those described in the paper. Though domestic welfare will differ, incentives to the foreign firm are not altered, and most propositions still remain robust. Further, the H-government could impose tariffs on first-period imports only, and let imports come in free in the second period. This then rewards high quality exports in the second period and home welfare might be improved. The same logic applies to incorporating multi-periods in the model. As the time horizon rises, the incentives to produce higher quality increase. Finally, instead of the experience-good approach, an alternative is to assume one period only and allow the foreign firm to produce mixed qualities, in which case multiple equilibria can arise and policy recommendations will become complicated.
