ABSTRACT

Purpose
The aim of the study was to compare long-term respiratory morbidity in children after repair of esophageal atresia (EA) or congenital diaphragmatic hernia (CDH).

Patients and methods
Children were seen at 6, 12, and 24 months and 5 years within a prospective longitudinal follow-up program in a tertiary children’s hospital. Respiratory morbidity and physical condition were evaluated at all moments. At age 5 years, pulmonary function and maximal exercise performance were tested.

Results
In 3 of 23 atresia patients and 10 of 20 hernia patients, bronchopulmonary dysplasia developed. Seventeen atresia and 11 hernia patients had recurrent respiratory tract infections mainly in the first years of life. At age 5, 25% of EA and CDH patients measured showed reduced forced expiratory volume in 1 second (z-score < -2). Both atresia and hernia patients showed impaired growth, with catch-up growth at 5 years in patients with EA but not in those with hernia. Maximal exercise performance was significantly below normal for both groups.

Conclusions
Esophageal atresia and CDH are associated with equal risk of long-term respiratory morbidity, growth impairment, and disturbed maximal exercise performance. Prospective follow-up of EA patients aimed at identifying respiratory problems other than tracheomalacia should be an integral part of interdisciplinary follow-up programs.
INTRODUCTION

Congenital diaphragmatic hernia (CDH) and esophageal atresia (EA) are both severe congenital anatomical anomalies requiring neonatal surgery and intensive care treatment. Follow-up for children with EA tends to focus on gastrointestinal pathologic condition. Respiratory pathologic condition, however, seems equally important and is widely described as related to the variable amount of tracheomalacia. Abnormal development of the tracheobronchial tree may contribute to tracheomalacia and recurrent atelectasis. Mild lung function abnormalities after EA repair have been described. Several cross-sectional studies report secondary morbidity. Up to 50% of EA patients were found to have associated anomalies such as cardiac anomalies and consequently higher morbidity. New treatment modalities such as high-frequency oscillation (HFO) ventilation, nitric oxide (NO) administration, and extracorporeal membrane oxygenation (ECMO) have improved survival rates in CDH patients. Evidence is emerging, however, that better survival coincides with a great deal of morbidity. Long-term pulmonary sequelae in CDH survivors seem to result not only from residual lung hypoplasia with persistent pulmonary hypertension but also from lung injury induced by ventilatory support. Other risk factors for morbidity are large diaphragmatic defects, ECMO therapy, and patch repair.

We hypothesized that children after repair of EA show the same extent of respiratory pathologic condition as CDH survivors, although probably of a different nature, with different causative mechanisms. The aim of the present study was to describe respiratory morbidity in EA and CDH patients with respect to baseline characteristics, respiratory tract infections (RTIs), lung function, and maximal exercise performance. In addition, we evaluated gastrointestinal morbidity and physical growth because these factors may influence the main end points with respect to respiratory morbidity. This is the first study to prospectively evaluate respiratory morbidity in EA patients at the age of 5 years.

METHODS

This longitudinal, observational, prospective, cohort study consists of repeated measurements at 6, 12, and 24 months and at 5 years.

Setting

The facility used for the study was the Pediatric Surgical Department of the Erasmus MC-Sophia Children’s Hospital, Rotterdam, the Netherlands. This is the only tertiary academic facility in the Southwestern part of the Netherlands equipped for all major surgical specialties. The referral area has 4 million inhabitants with 44,000 newborns annually.
Since 1999, a multidisciplinary team - consisting of a consultant senior pediatric surgeon, pediatricians, psychologists, a pediatric physiotherapist, nurses, and a social worker- runs a follow-up program for children born with a major anatomical malformation and their families. A clinical geneticist was added to the team in 2004. The program aims to reduce the overall morbidity associated with these malformations, in particular, the index diagnoses as described by Ravitch.19

Patients
All 68 patients with EA and CDH admitted to the ICU of our department within 7 days after birth from January 1999 to February 2003 were eligible for this study. For the present study, we excluded data from 4 patients having infections and growth impairment as a result of a major syndromal or chromosomal anomaly itself (EA, n = 3, 2 Down’s syndrome and 1 undefined; CDH, n = 1, Wolf-Hirschhorn syndrome). Data of the 16 children who died within 6 months were excluded as well. Five families did not participate in our follow-up program. Thus, 43 children (82.7% of survivors) completed a 5-year follow-up (Figure 1).

Figure 1 Flowchart showing group composition
Procedure

The Erasmus MC ethical review board agreed with the study, and written parental informed consent was obtained for all subjects. Demographic and medical data were collected prospectively from the first day of admission. A clinical geneticist routinely evaluated major chromosomal, syndromal and cerebral abnormalities during admission. By protocol, the children were seen at ages 6, 12, and 24 months and 5 years, corrected for gestational age. Age for the final evaluation ranged from 5 to 6.5 years.

General aspects

At each time-point, a pediatrician performed a full physical examination including neurologic examination according to the method of Touwen.20 A senior pediatric surgeon evaluated specific pediatric surgical issues. Weight and height were measured, and body mass index (BMI) was calculated. Growth data for the Dutch population served as reference values21,22 and standard deviation scores (SDS) were calculated using Growth Analyser version 3.5 (Dutch Growth Foundation, Rotterdam, The Netherlands). Reference values for Dutch children of Moroccan or Turkish origin were used if applicable.23,24

Respiratory morbidity

The incidence and severity of bronchopulmonary dysplasia (BPD) were recorded according to the diagnostic criteria of Jobe and Bancalari.25

At each time-point, therapeutic and prophylactic courses of antibiotic treatment, use of inhaled bronchodilators and steroids, and readmissions for RTI were recorded. We recorded numbers of RTI during the first, the second, and the third to fifth years, respectively. At the age of 5 years, 38 children (EA patients, n = 20, and CDH patients, n = 18) performed pulmonary function tests as follows: we obtained flow-volume curves before and after bronchodilation with 400 μg of salbutamol and measured the fraction of exhaled NO (FE\textsubscript{NO}). Flow-volume curves were measured on a Masterscreen electronic spirometer (Jaeger, Würzburg, Germany). Forced expiratory volume in 1 second (FEV\textsubscript{1}) was expressed as percentage predicted. Fraction of exhaled NO was measured online according to guidelines from the European Respiratory Society and American Thoracic Society using the NIOX analyzer (Aerocrine, Solna, Sweden).26

Maximal exercise performance

At 5 years, the children performed a graded, maximum exercise test using a motor-driven treadmill (En Mill, Enraf Nonius, Rotterdam, the Netherlands) programmed for increases in angle of inclination and speed according to the Bruce protocol.27

The children were encouraged to perform to voluntary exhaustion. The maximal endurance time (in minutes, one decimal) served as criterion of exercise capacity, with
SDS based on recently established reference values for healthy Dutch children (personal communication, van der Cammen-van Zijp, May 2008). Before, during, and at 2 and 5 minutes after the test, children's heart rate and transcutaneous oxygen saturation were monitored with a pulse oximeter (MARS [motion artifact system], type 2001, Respironics Novametrix, Murrysville, Pa). Heart rate of at least 185 beats per minute or loss of coordination was considered to indicate maximal performance.28

Gastrointestinal morbidity
Children were evaluated for gastroesophageal reflux (GER) by barium swallow x-ray and pH-metry as previously described by Bergmeijer.29,30 Gastrointestinal symptoms, use of medication, surgical treatment of reflux, and consultation of a dietician were recorded as well.

Data analyses
Descriptive statistics were calculated for baseline characteristics and outcome variables. We performed group comparisons with the Mann-Whitney U test. Growth parameters and SDS maximal endurance time were compared with the reference values using t-tests for independent samples (1-tailed). Statistical significance was accepted at 5% level. SPSS 15.0 for Windows (SPSS, Chicago, Ill) was used for data analyses.

RESULTS
Baseline characteristics for both groups of children are shown in Table 1. All CDH patients were born after a gestational age of at least 36 weeks; 4 EA patients were born before 36 weeks of gestation at 28, 29, 31, and 33 weeks, respectively. All but one EA children underwent primary anastomosis via a lateral thoracotomy within 48 hours. One patient had a type A long gap atresia and underwent delayed primary anastomosis after 3 months. Bronchoscopic evaluation of tracheomalacia during the initial repair was not routinely performed. In 15 of the 20 children with CDH (75%), the diaphragmatic defect was repaired with a Gore-Tex patch (WL Gore and Associates, Flagstaff, Ariz). Only one child had a right-sided CDH (5%). Diaphragmatic repair was by subcostal laparotomy in all cases.

In neither group complex heart defects were found. For both groups, the major impact of morbidity was during the first year of life; hospital admissions occurred mainly in the first 6 months and surgical interventions within the first year. Surgical interventions in EA patients comprised mainly dilations of anastomotic esophageal strictures (in 70% of EA patients, n = 16, median 2 per patient, range 0 - 9) and Nissen fundoplications (n = 8, 34.8%). Aortopexies had not been performed.

CA: congenital anomaly, ASD: atrial septal defect, VSD: ventricular septal defect

Additional medical problems at discharge varied from GER (n = 21 EA; n = 18 CDH) to atopic eczema and were mainly (> 80% for each group) related to the primary congenital anomaly. At discharge, 21 (87%) of EA patients and all CDH patients received medication. These figures had dropped to 43.5% and 23.8% at the age of 5 years, respectively.

**Respiratory morbidity**

All EA patients had been ventilated conventionally. Three children (13%) with severe tracheomalacia developed BPD (Table 2), and bronchoscopy was performed only in these 3 patients. None of the EA patients received ECMO treatment.

Eight CDH patients (40%) were primarily ventilated with HFO and had been converted to conventional ventilation before surgical closure of the diaphragm. Four (33.3%) of the conventionally ventilated CDH patients were later converted to HFO ventilation. Venoarterial ECMO was performed in 11 CDH patients (55%), starting at a median age of 13 (range 5 - 265) hours. Extracorporeal membrane oxygenation was discontinued after a median of 168 (72 - 459) hours.

Routine vaccination against respiratory syncytial virus and/or influenza was not performed.

Table 2 gives details of the respiratory morbidity encountered during the 5 years of follow-up. Both EA patients born before 30 weeks of gestation developed BPD; only one of them had recurrent RTI. Nine (81.1%) of 11 ECMO-treated CDH patients and one other developed moderate or severe BPD. Of these 10, 5 (50%) had recurrent RTI. Recurrent RTI were also reported in 6 CDH patients (60%) who had absence of or only mild BPD. One prematurely born EA patient and both CDH patients with a cardiac anomaly developed BPD. None of them had recurrent RTI. Hospitalizations for RTI were rare. Median numbers of RTI are relatively low but show wide ranges in both groups.

Spirometry before and after bronchodilation was initiated in 38 patients at 5 years; 5 patients were not examined because of parental refusal (n = 2), for practical reasons (n = 2), or because of mental retardation (n = 1). Most patients, however, failed to perform reproducible flow-volume curves. Forced expiratory volume in 1 second and FE\textsubscript{NO} were the only 2 reliably obtained lung function parameters (Table 2). In both groups, 25% (n = 12 EA, 8 CDH) of patients had abnormally low percentage of predicted of FE\textsubscript{V1}. The median FE\textsubscript{NO} was within the predicted range for (n = 9) EA patients (9.0 parts-per-billion) and in the lower range of normal for (n = 9) CDH patients (5.2 parts-per-billion).\textsuperscript{31}

**Maximal exercise performance**

One EA patient and 2 CDH patients could not perform the maximal exercise test because of neurologic underlying disease such as cerebral palsy. Thus, 22 EA patients and 18 CDH patients performed the exercise test. Reliable results could not be obtained for 6 EA patients for the following reasons: no maximal exercise performance reached (n = 3); balance problems (n = 2); and poor concentration (n = 1). Results for 2 of the CDH patients were unreliable because of balance problems or unwillingness to perform maximally (n = 1 for each reason).

Both in EA (n = 16) and CDH (n = 16) patients, the maximal exercise tolerance was significantly below the norm (mean SDS endurance time, -0.60; p = 0.02, and -0.84; p = 0.012, respectively). One EA patient (6.3%) and 2 CDH patients (12.5%) had an abnormally low maximal exercise tolerance (ie, maximal endurance time SDS < −2; not significant). The median (range) heart rate at maximal exercise was 181 (194 - 148) and 191 (207 - 146) beats per minute for the EA and CDH group, respectively. Two EA patients (12.5%) had a decreased oxygen saturation (ie, ≤ 94%) at maximal exercise (94 and 93%, respectively). This phenomenon was not observed in any of the CDH patients.
Figure 2(a, b, and c) Diagram representing the mean (SD) for height (a), weight (b), and BMI (c) across time in CDH and EA patients. Circles and solid lines represent CDH; open triangles and dashed lines represent EA. * signals significant deviation from the Dutch norm at the 5% level ($p \leq 0.05$), ** signals significant deviation from this norm at the 0.1% level ($p \leq 0.001$).
Gastrointestinal morbidity
In both groups, 20 children were treated conservatively with antacids and prokinetic drugs initially. Thirteen EA patients and 11 CDH patients also received an acid secretion inhibitor. Eight EA patients (34.8%) and 7 CDH patients (35%), respectively, underwent a Nissen fundoplication. For those patients who were treated conservatively, the median (range) duration of treatment of GER was 23.11 (0 - 71.7) and 8.0 (0 - 64.9) months in EA and CDH, respectively. Patients with EA who underwent a Nissen fundoplication had a median number of 9.5 RTI in 5 years (range, 0 - 23) vs 7 (3 - 24) for those treated conservatively (NS). Corresponding figures for the CDH patients are 9 (1 - 17) vs 7 (0 - 14) (NS). There was no significant difference in RTI before or after the Nissen fundoplication.

A dietician was consulted for 8 patients in each group.

Physical growth
Data at 6, 12, 24, and 60 months for both groups are shown in Figure 2. At 5 years of age, EA patients seemed to catch up in weight, concomitant with an increase in height (Figure 2b and a). The BMI SDS was constant after the first year of life for both groups but reached a higher level for EA patients (Figure 2c).

Extracorporeal membrane oxygenation-treated CDH patients had a significantly lower height at 6 months, 12 months, and 5 years (p = 0.02, 0.04, and 0.04, respectively), lower weight at 12 months and 5 years (p = 0.02 and 0.02, respectively), and lower BMI at 12 months of age (p = 0.05) than non-ECMO-treated CDH patients.

DISCUSSION
We prospectively evaluated respiratory morbidity and factors interrelating with pulmonary disease during the first 5 years in 2 groups of children born with major congenital anatomical malformations of the respiratory tract: EA and CDH. Both groups showed recurrent respiratory tract infections, abnormally low FEV$_1$ in 25% of patients, no increase of FE$_{NO}$ levels, and decreased maximal exercise tolerance. In addition, a high incidence of GER and impaired physical growth were observed in both groups.

Tracheomalacia associated with EA occurs frequently and may lead to respiratory insults.\textsuperscript{32} Less frequent are RTIs, wheezing, and cough; these findings mainly are derived from studies using a cross-sectional design.\textsuperscript{33-36} Results, especially regarding RTIs, therefore may have been influenced by recall bias. Dudley and Phelan\textsuperscript{37} retrospectively evaluated 192 EA survivors and found that 78 children had experienced more than 3 episodes of bronchitis per year in the first 3 years of life. More recent, Malmström et al\textsuperscript{34}
showed that 41% of adolescents after repair of EA still had respiratory symptoms, and 52% had ever had pneumonia or wheezing. Pneumonia in the first years of life may give rise to mild lung function abnormalities later in life.38 Our prospectively collected data are consistent with these findings. In addition, we showed that these problems might negatively affect maximal exercise tolerance. Only 3 EA patients with severe tracheomalacia required prolonged ventilation and developed BPD, whereas 10 (50%) CDH patients, mainly those treated with ECMO, had moderate to severe BPD according to criteria of Jobe and Bancalari.25 We assume, therefore, that different mechanisms are involved in persisting respiratory morbidity. In CDH patients, the susceptibility of the hypoplastic lungs for artificial ventilatory support is well documented.13,39,40

In both groups, the frequency of RTI at any measurement moment did not differ between children who underwent a Nissen fundoplication for GER or those who were treated conservatively. We assume that reflux in these patients is not a major contributor to RTI.

Interestingly, hospital admissions for RTI were hardly needed, and therapeutic antibiotic courses had not always been prescribed. This suggests that many RTIs showed a relatively mild course and were of nonbacterial origin.

As sample sizes were limited and numbers of possible contributing factors large, we did not perform regression analysis to predict respiratory morbidity. Still, we evaluated several factors that might have contributed to RTI. Being rare in either group, cardiac anomalies did not seem to influence incidences of RTI within the first 5 years. Because 50% to 60% of CDH patients showed recurrent RTI irrespective of BPD, we assume that extrapulmonary factors may be involved as well. Most patients in either group had gastrointestinal problems and impaired physical growth. These factors may well contribute to increased susceptibility for RTI. Nevertheless, the impact of gastrointestinal problems on RTI in EA patients remains inconclusive so far.34,37,38

Pulmonary function testing proved problematic. For no more than half of the patients (n = 20), we could interpret FEV₁ before bronchodilation. This revealed airflow obstruction in 25% of them. From the literature, it appears that pulmonary function testing was successful in 40% to 83% of 5-year-old children.41

Fraction of exhaled NO is known to be associated with eosinophilic airway inflammation.31,42 Almost all patients in the present study had normal FE(NO) levels, in line with findings by Malmström et al.34 The FE(NO) level was increased in only one CDH patient, who showed an atopic constitution. Low or normal FE(NO) levels have also been described in children with bronchopulmonary dysplasia,25 which might explain the lower median FE(NO) in the CDH patients.
Both EA and CDH patients showed lower maximal exercise tolerance compared with recently established reference values for healthy Dutch children (personal communication, Van der Cammen-van Zijp). Persistent respiratory morbidity and impaired growth may contribute to this phenomenon.

In spite of gastrointestinal and nutritional morbidity, especially in the first year for EA patients, only 13% of parents consulted with a dietician during the child’s first year of life. For the CDH patients, failure to thrive remained a problem over time. Lack of catch-up growth was mainly seen in ECMO-treated CDH patients. We assume that they have more severe lung hypoplasia requiring intensive work of breathing. Patch repair, GER, and recurrent RTI may also contribute, but our data do not allow for hard conclusions. Attempts should be undertaken to improve energy intake as work of breathing may require a higher energy intake in CDH and, to a lesser extent, EA patients.

Multidisciplinary follow-up of surgical newborns has hardly been performed so far but has recently been advocated by the American Academy of Pediatrics for CDH patients. The groups of Muratore and Friedman, however, have reported retrospectively collected data on pulmonary, gastrointestinal, and neurodevelopmental morbidity in CDH patients up to 3 years of age in a multidisciplinary follow-up clinic. It appeared that these showed continued pulmonary and gastrointestinal morbidity over the years, such as the CDH patients in the present study, who show the same pathologic condition up to the age of 5 years.

In conclusion, both EA and CDH patients are at risk for long-term respiratory morbidity, disturbed maximal exercise performance, and growth impairment. Prospective evaluation of EA patients aimed at identifying other respiratory problems than tracheomalacia should be an integral part of postoperative interdisciplinary follow-up programs.
