## FOREWORD

The study, described in this thesis, was carried out in the Dept. Obstetrics and Gynaecology (Head: Prof.Dr. A.C. Drogendijk), of the Academic Hospital Dijkzigt, Rotterdam, Holland, under the guidance of Prof.Dr. J.W. Wladimiroff. Till the very last moment he has provided unfailing enthusiasm enabling the fruition of this thesis. For this I am very grateful.

The critical remarks and advice from Prof.Dr. A. Versprille, the second Promotor, were extremely valuable to me.

I owe a great debt of gratitude to Prof.Dr.Ir. N. Bom and Prof.Jhr. V.H. de Villeneuve for their willingness to act as Referees.

In the first phase of the practical part of the study, I was helped a great deal by Wim Vletter of the Dept. Echocardiology. Later Leo Vrij and John Wondergem performed many of the recordings during their elective period and as student-assistants. I would like to acknowledge their help.

The contacts with the Dept. Experimental Echocardiography were very useful. Mr. G. van Zwieten wrote the computer programmes for the calculation of the collected data.

Mr. C. Ligtoet advised me about the description of the technical aspects of the ultrasound investigation.

Mr. H.J.A. Schouten of the Dept. Biostatistics gave useful statistical advice concerning the results of the study.

Patricia Stewart spent a lot of time correcting the English text of this thesis.

I would like to thank Alize Bijl for the efficient way in which she typed this manuscript.

Finally a word of thanks to all who were in any way connected with this study.

This thesis is dedicated to my parents, who have provided life long love, support and encouragement.

## Chapter 1

### INTRODUCTORY REMARKS AND DEFINITION OF OBJECTIVES OF THE PRESENT STUDY

The first documentation pertaining to the fetal cardiovascular system is attributed to Galenus, who in the Second Century A.D. described what was later to become known as the foramen ovale and its valve, as well as the ductus arteriosus and gave some account of their postnatal closure. It was not until 1564 that a posthumous publication, originating from Vesalius, contained the first account of the ductus venosus. In 1626, also in a posthumous publication from Spigelius, it was pointed out that no direct communication exists between the umbilical vessels of the fetus and the uterine vessels of the mother. He also observed that in the fetus the left and right ventricular walls are of about equal thickness, whereas in the adult the left ventricular wall predominates. Two years later, in 1628, William Harvey introduced his concept of the circulation of blood which included the first account of the fetal circulation. This publication marked the beginning of the use of a dynamic concept of the cardiovascular system. It was not until the present century that methods of experimental research were applied to the problems related to the fetal circulation. In 1907, Pohlman pointed out the need for the use of experimental methods in live animals in this particular field. His experiments consisted of the injection of corn starch granules into the circulation of fetal pigs. Huggett (1927) found, in the exteriorized fetal goat, a higher oxygen content in carotid arterial blood than in blood from the descending aorta. In this study, he was able to refute the longstanding concept (Sabatier, 1778) that although well-oxygenated blood was directed preferentially to the ascending aorta to supply the heart and brain, the rest was returned to the placenta. Further impetus to research in fetal and neonatal cardiovascular physiology was given by

Barclay, Franklin and Prichard (1944) and by Sir Joseph Barcroft (1946). The first group introduced cineröntgen techniques into the study of the circulation in the fetal and neonatal lamb. To a great extent, Lind, Stern and Wegelius (1964) have also used angiographic techniques to study human fetal and neonatal circulation. Recently, several different techniques have been applied to the study of the heart and circulation of the fetus and newborn, i.e. observations of early embryonic hearts and individual embryonic myocardial cells in tissue culture (Zak, 1973), study of the responses of isolated papillary muscles in tissue baths (Boerth, 1972; Friedman, 1973). Most of our present knowledge of fetal and neonatal cardiovascular anatomy and function, however, was derived from lamb experiments; in particular by Dawes and co-workers in Oxford (Dawes, 1968) and Rudolph and co-workers in San Francisco (Rudolph and Heymann, 1974). Data were originally collected from the exteriorized preparation, although it became increasingly evident that the exteriorized fetus underwent major physiological circulatory changes. Acute observations of the fetus in utero resulted in more meaningful data, but once more it was evident that many physiological functions were affected by the surgical and anaesthetic procedures introduced. This led to studies of the fetus in utero after recovery from the effects of surgery in chronic preparation. Rudolph and Heymann (1974) pointed out that these chronic preparations may still not be indicative of the normal physiological state, if only for the high incidence of spontaneous parturitions up to a week following surgical intervention.

The non-invasive nature of diagnostic ultrasound examinations allowed observations of the human fetal and neonatal heart with no interference to the normal physiological state. Examinations of the fetal heart by means of pulsed ultrasound dates back to 1954 when Edler and Hertz were the first to obtain motion patterns of fetal cardiac structures. Later, Robinson (1968) reported on the identification of the intra-

ventricular septum. Fetal heart volume measurements were made by Garrett and Robinson (1970) and Suzuki et al (1974) and more detailed analysis of fetal cardiac anatomy became possible as a result of the introduction of grey-scale techniques (Lee et al, 1977). It was not until the introduction of real-time scanners that information on cardiac anatomy in relation to the various stages of the cardiac cycle could be obtained. The introduction of dynamically focussing linear array real-time systems, resulting in high resolution images, has opened-up the possibility of obtaining information on cardiac geometry and function from a two-dimensional display (Wladimiroff and McGhie, 1981a). Combined use of two-dimensional real-time ultrasound and single beam transducers opened the possibility of studying the fetal and neonatal heart from time-motion (M-mode) recordings (Hobbins et al, 1978; Wladimiroff et al, 1979).

The objective of the present study was to obtain an answer to the following questions:

- Does an ultrasound time-motion recording of the fetal and neonatal heart allow accurate and reproducible measurements of ventricular size and intraventricular septum thickness during the various stages of the cardiac cycle.
- If so, do these time-motion recordings contribute in a meaningful way to our present knowledge of human fetal and neonatal cardiac ventricular geometry and function, both under physiological and pathophysiological circumstances.
- When the ventricles are functionally alike, the systolic pressure rise on both sides of the septum will be about the same. Is it possible to use ultrasound, and in particular study of septal motion and thickening in the fetus to support the hypothesis that the fetal septum does not play a role during ventricular contraction.

## Chapter 2

### SOME BASIC PRINCIPLES OF DIAGNOSTIC ULTRASOUND PARTICULARLY WITH RESPECT TO THE M-MODE RECORDING

For medical diagnostic applications, sound waves (longitudinal pressure waves) at frequencies in the 1 to 10 MHz range must be employed to obtain the required resolution. These high-frequency sound waves travel through a medium at a velocity characteristic of that medium. On reaching an interface with another medium of different acoustic properties, the ultrasound beam may be reflected. The acoustic impedance of a medium is the product of the velocity of sound in that medium and the density of that medium. At an interface between media of different acoustic impedances, a component of the sound wave energy will be reflected (echo) while another component of the energy will be transmitted into the second medium etc. The amplitude of the echoes is determined by:

- the difference in acoustic impedance between two media. The echo amplitude from an interface between blood and muscle tissue is smaller than that originating from an interface between bone and water;
- the emitted sound energy;
- the angle of the sound wave to the reflecting interface. Since the reflection of energy is such that the angle of incidence equals the angle of reflection, optimal echo information will be obtained when the angle between the sound beam and reflecting interface is perpendicular;
- the attenuation during passage of sound waves through a medium. This attenuation is exponential and therefore is expressed in the logarithmic dB notation. Thus an ultrasound wave is rapidly attenuated by passage through tissue so that the incident intensity on a deeply situated interface will be very small as compared with the incident intensity on a superficially situated interface.

## 2.1 Basic principles of an echosystem

Fig. 2.1 shows the block diagram of an echosystem. The timer generates a starting signal for the complete system. After receiving this signal, the pulse transmitter provides electrical energy for the transducer at the desired ultrasound frequency (probe). This electrical energy is converted into acoustic energy by piezo-electric material in the transducer. In this way a sound wave is generated, which travels into the patient. Simultaneously the horizontal deflection of an oscilloscope is triggered, which starts a line on the oscilloscope screen. After the transmission of the sound wave into the patient, the system is switched into reception. The reflected sound wave (echo) is received by the transducer and converted into an electrical signal by the same piezo-electric

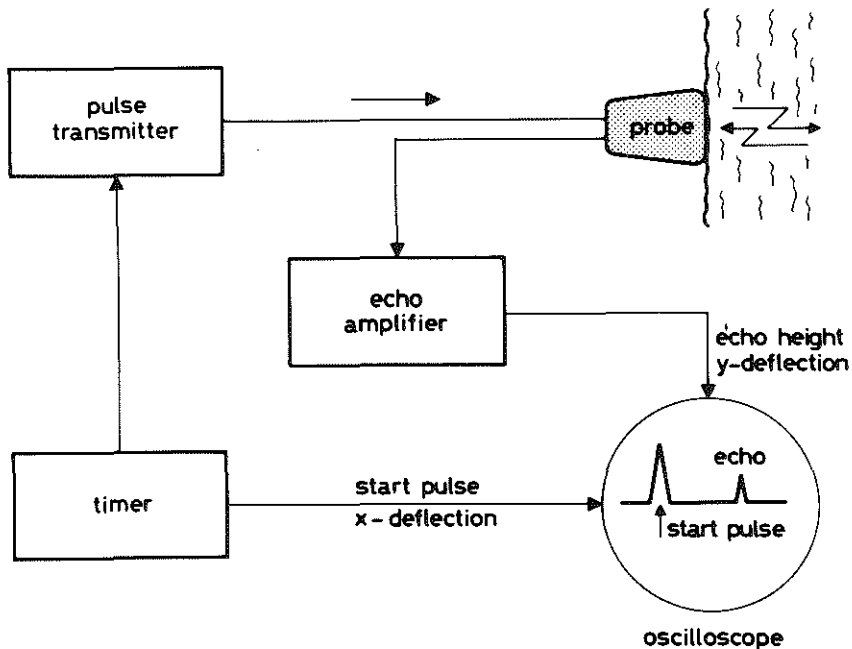

Fig. 2.1 Block diagram of an echosystem. Explanation in text.

material. This signal is amplified (echo-amplifier) and displayed on the oscilloscope as a spike. The distance between the starting point and the spike on the screen is proportional to the distance of the transducer and the structure which generates the echo. The amplification section of the echo-system is capable of amplifying weak signals, generated deep inside the body, more than the strong echoes, generated by structures near the transducer. This mechanism is called time gain amplification. The amplitude of the echoes can be recorded in terms of the amplitude of the Y-deflection of the oscilloscope. This type is known as the A-mode, i.e. amplitude mode. An echo can also be displayed in the Brightness-mode the so-called B-mode. In this type of display, the larger the echo, the brighter the spot on the oscilloscope screen. The M-mode records the movement of reflecting structures along a single sound beam as a function of time, i.e. Motion-mode.

## 2.2 M-mode information

It is particularly the M-mode information, which will be more extensively discussed, since all data presented in this thesis were obtained from M-mode recordings. The M-mode technique yields information with a high sampling rate along a single sound beam. The recorded variable is the distance between the reflecting surfaces and the transducer as a function of time. The M-mode will only display movements which occur in the path of the ultrasound beam (Paragraph 2.3). The line of ultrasonic data on the oscilloscope screen is brightness modulated. Due to the high repetition rate echoes will show as moving dots on this line. The movement of these dots can be recorded on paper or on the oscilloscope screen itself by

- a. movement of light sensitive paper in front of the bright line
- b. electronic displacement of the subsequent echo lines on the oscilloscope screen, such that the adjacent lines

produce the well-known M-mode.

The great advantage of the M-mode technique is that changes in distance between two anatomical structures can be studied. The quality of the M-mode recording is subject to a number of factors. In the first place there are certain limiting factors with respect to the physical properties of ultrasound. Secondly, M-mode recordings only allow analysis of ultrasound information originating from one direction. Thirdly, considerable expertise is required to obtain and interpret M-mode recordings.

## 2.3 Limitations of the M-mode technique

### 2.3.1 Reverberations

Strongly reflecting interfaces may produce echoes, which will travel backward and forward several times, i.e. reverberations, before ultimately reaching the transducer. Under these circumstances, there will be a lengthening of the time interval between emission of the ultrasound wave and subsequent reception of the echo resulting in so-called 'mirror images' (Fig. 2.2).

### 2.3.2 Resolution problems

There are two types of resolution: axial and lateral resolution. The axial resolution is the ability of a system to differentiate in the axial direction between two reflectors which are situated in the beam of the transducer. The axial resolution depends on the brevity of the ultrasound pulse. With high ultrasound frequencies short ultrasound pulses may become possible. However, at high frequencies stronger attenuation exists. It is therefore necessary to find a compromise between axial resolution and penetration depth.

Fig. 2.2 This figure illustrates the mechanism of reverberations between two strongly reflecting boundaries. Additional echoes appear on the display behind the echoes whose position represents the correct boundaries.

The lateral resolution is the ability of a system to differentiate between two reflectors which are situated in a plane at right angles to the sound beam. The display of these reflectors is very much dependent on the profile of the ultrasound beam. The area which is covered by the ultrasound beam can be divided into a 'near field' and a 'far field'. In the 'near field' the beam width is virtually equal to the transducer width, whereas in the 'far field' the beam will diverge. All echoes from structures which are situated within the ultrasound beam, will be received by the transducer.

Focussing techniques may improve the shape of the ultrasound beam and thus, the lateral resolution. Focussing systems are now incorporated in all present ultrasound scanners.

### 2.3.3 Amplification problems

Echoes from deeply situated structures will be small as compared with echoes from near structures. However, as already mentioned, selective amplification can be added to compensate for ultrasound attenuation (time gain compensation). Since attenuation varies from patient to patient, it means that the time gain compensation has to be optimally adjusted by hand in every patient, in order to achieve a display from which echoes of various amplitudes are well represented.

Reverberation might occur when the amplification is too large, and essential structures may be missed when it is too small. Both may lead to erroneous interpretations.

### 2.3.4 Directional problems

The M-mode technique will only allow recording of echo information from one dimension. Information from more than one dimension, i.e. from adjacent structures can be obtained by slowly moving the M-mode transducer during the examination. However, it should be realized that when using M-mode, movement of the adjacent structures can never be visualized simultaneously. In other words, the M-mode technique, in contrast to two-dimensional real-time systems does not allow us to study structural movements in relation to their anatomy. Detailed knowledge of the anatomy of the structure is essential, when carrying out M-mode studies. At present, M-mode systems are nearly always employed in combination with two-dimensional real-time scanners.

## 2.4 The actual M-mode recording

In the present study a single element technique (2.25 MHz) and line selection from a dynamically focussed linear array (3.1 MHz) real-time system (Organon Teknika) were used.

A single element transducer (Fig. 2.3) is built up with one disc shaped piece of piezo-electric material.

Fig. 2.3 Single element transducer.

In contrast, the transducer of a linear array system contains many rectangular shaped small piezo-electric elements in a row. A combination of  $n$  adjacent elements is selected to produce a scan. The next scan is made with  $n-1$  elements of the previous scan and one new adjacent element. In this way a large number of scans is produced by selecting different combinations of adjacent elements. Each scan is displayed in B-mode on an oscilloscope screen, relative to its position. Consequently a two-dimensional image is displayed, built up from a larger

number of scans. Fast switching provides 50 images a second, which means that moving structures can be studied within their anatomical relationship. One scan in this image can be selected for M-mode registration. The advantage of selecting an M-mode line from a two-dimensional image is the possibility of aiming the M-mode scan at the desired structures.

## 2.5 Analysis of the M-mode tracing

As has been said before, the M-mode contains information about the depth of the echo producing structure relative to the transducer and about the movement patterns of that particular structure. During the M-mode recording, calibration dots are introduced, allowing measurements of the velocity with which the structure moves. Fig. 2.4 depicts the calibration dots in an M-mode tracing of the fetal heart. On the vertical axis (depth), the distance between two dots is 1 cm, whereas on the horizontal axis (time), the distance is 0.5 sec. Measurements can be carried-out using compasses. It is clear, however, that this would be a very laborious procedure particularly when a large amount of information has to be collected. In the present study, therefore, M-mode echocardiograms were analysed using a computer system with a digitizing tablet and light pen (Bit Pad one: resolution 0.1 mm, accuracy  $\pm$  0.081). Fig. 2.5 is a drawing to show the composition of this equipment with data analysing facilities. After tracing of the essential features of an M-mode recording, the computing system can determine variables during one or more cardiac cycles. The analysis starts with a command for calibration. This is possible by indicating three points on the recording with the pen in the rectangular co-ordinate system of the digitizing tablet: an origin (free choice), a corresponding point 1 second later and a point 5 cm above the origin. After calibration the right and left ventricular endocardial wall echoes, and the intra-ventricular septum echoes are traced for ten cardiac cycles. The digitized data are translocated, rotated and scaled

according to the calibration points. The data are filtered by a low-pass filter to remove hand tracing errors and are stored in a fixed element array in memory. The sampling points in this array are equally spaced in time.

The cardiac structures, which were measured as described above, will be discussed in Paragraph 3.2.

Fig. 2.4 M-mode of a fetal heart, displaying the calibration dots as described in paragraph 2.5.

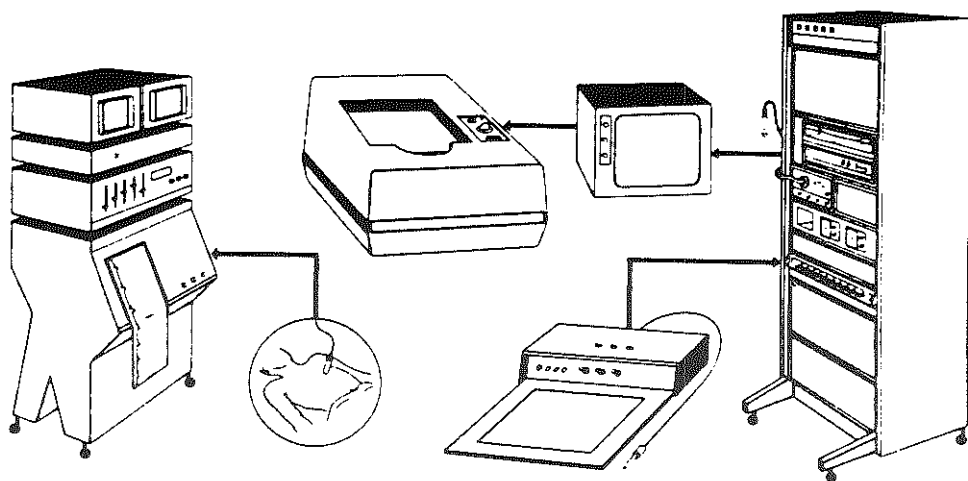

Fig. 2.5 A schematic drawing of the echocardiographic data equipment. The ultrasound system is shown to the left. The digitizing tablet and video hard copy device are shown in the middle and the computer configuration to the right.

## Chapter 3

### M-MODE RECORDING OF THE FETAL AND NEONATAL CARDIAC VENTRICLES. TECHNIQUE, ANALYSIS AND REPRODUCIBILITY OF THE MEASUREMENTS

In this chapter the technique of obtaining an M-mode recording of the fetal and neonatal ventricles will be described first.

#### 3.1 M-mode recording techniques

M-mode recordings were made both during fetal and early neonatal life. They will be described separately.

##### 3.1.1 The antenatal period

The examination procedure begins with a search for the two-dimensional image of the largest longitudinal cross-section through the left and right fetal ventricle by means of a dynamically focussing linear array real-time scanner (Organon Teknika) (Wladimiroff et al, 1979). The first step consists of determining in a cross-section the position of the fetal spine and chest in the maternal abdomen. In the next step the transducer is placed at the level of the fetal heart, in a plane at an angle of  $45^{\circ}$  to the antero-posterior axis of the fetal chest and at an angle of  $50^{\circ}$  to the fetal spine (Fig. 3.1). This plane will run through the right and left ventricle at right angles to the intraventricular septum. The third step represents the identification of the largest cross-section through the right and left ventricle by making scans parallel to the scanning plane described until the following five landmarks are visible on the two-dimensional image (Fig. 3.2): the left ventricular posterior wall (PW), the intraventricular septum (IVS), the right ventricular anterior wall (AW), the mitral valve leaflets (MV) and aortic

root (Ao). The continuous visualization of these five landmarks allows the plane of investigation to remain virtually unchanged both during the systolic and diastolic phase of the cardiac cycle.

Fig. 3.1 Schematic representation of the transducer position at right angles to the plane through the intraventricular septum (hatched area) of the fetal heart. Explanation in text. (Courtesy of the Brit.J.Obstet.Gynaec.)

Fig. 3.2 Real-time two-dimensional scan and schematic picture of a longitudinal cross-section through the left ventricle (LV) and right ventricle (RV) depicting the right ventricular anterior wall (AW), the intraventricular septum (IVS), the left ventricular posterior wall (PW), the mitral valve leaflets (MV), the aortic root (Ao), and the posteromedial papillary muscle (P). T and L represent the largest transverse and longitudinal diameter of the left ventricle (LV) (Courtesy of the Brit.J. Obstet.Gynaec.)

For further clarification, Fig. 3.3 depicts a similar scanning plane on a post mortem specimen of a fetal heart at 39 weeks of gestation. This specimen does not show the aortic root. It should be realized that when the fetus is situated with the spine in the right lateral position, the ultrasonic beam will first traverse the left ventricle; when the fetal spine is situated in the left lateral position, the right ventricle will be approached first (Fig. 3.4). In the last step of the procedure a line is selected in the two-dimensional real-time image as described in Chapter 2, which runs through the left

and right ventricle at right angles to the intraventricular septum and is situated at the level of the mitral valve leaflets (Fig. 3.2). An M-mode recording of the cardiac structures along this line is subsequently made (Fig. 3.5) depicting the left and right ventricle (LV and RV), the intraventricular septum (IVS), the left ventricular posterior wall (LVPW), the right ventricular anterior wall (RVAW) and the mitral valve leaflets (MV). Particular attention was paid to optimal visualization of the ventricular endocardium by means of correct time gain setting.

Fig. 3.3 Longitudinal cross-section through a post mortem fetal heart at 39 weeks of gestation.

Fig. 3.4 Transducer positioning relative to the fetal chest and heart. A = anterior, P = posterior, R = right, L = left, SP = spine, LV and RV = left and right ventricle. When the spine is situated on the right (right), the ultrasonic beam will first traverse the left ventricle. When the spine is situated on the left (left), the ultrasonic beam will first traverse the right ventricle.

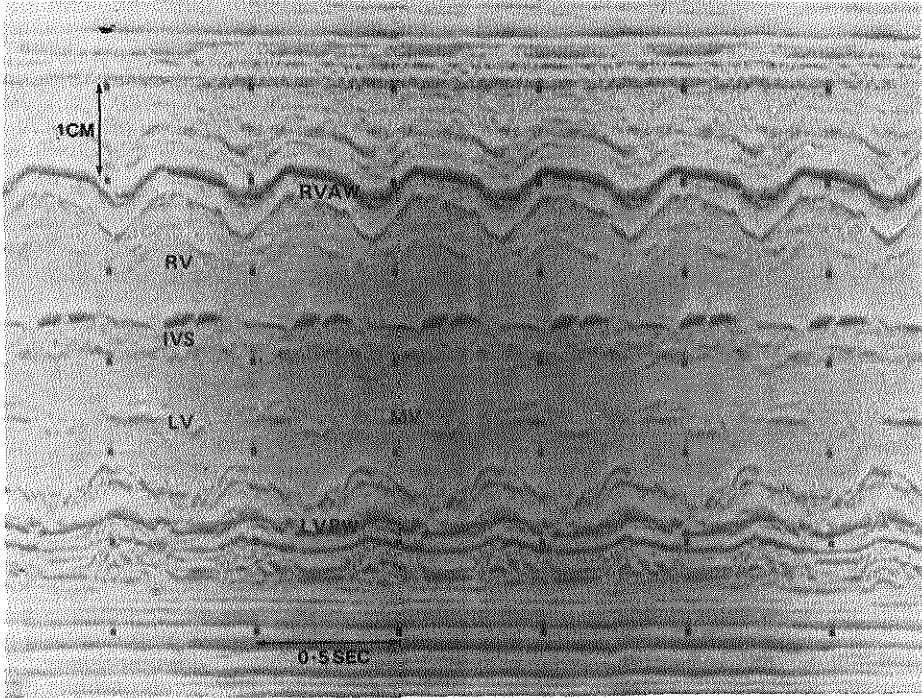

Fig. 3.5 Example of an antenatal M-mode recording. LV = left ventricle, RV = right ventricle, IVS = intraventricular septum, LVPW = left ventricular posterior wall, RVAW = right ventricular anterior wall, MV = mitral valve leaflets.

### 3.1.2 The early neonatal period

During the neonatal period a single element transducer as described in Chapter 2 was used. In contrast to the fetal study, real-time ultrasound orientation of the position of the heart is not necessary in the neonate. The infant is slightly turned to the left-lateral position to avoid possible interference of sound absorbing lung tissue between heart and

transducer. The single element transducer is first positioned in the left parasternal region of the chest at the level of the 2nd intercostal space. The mitral valve is used as a landmark. The sequential directions of the sound beam in the sagittal plane of the left ventricle through the long axis from the aorta to the apex are schematically shown in Fig. 3.6.

Fig. 3.6 Schematic longitudinal cross-section of the neonatal heart.

A scan is performed when the transducer is swept from the aorta (direction 1) towards the apex (direction 4). Explanation in text.

The resulting M-mode scan is represented in Fig. 3.7.

Fig. 3.7 M-mode scan of the neonatal heart following the sagittal plane through the long axis of the left ventricle. The directions of the sound beam labelled 1 to 4 on the diagram of Fig. 3.6 correspond to the areas labelled 1 to 4 on this record.

Four anatomic areas with specific cardiac structures and motion patterns corresponding to basic transducer directions, must be distinguished (Roelandt, 1977).

#### Area 1.

This area is recorded when the sound beam is aimed from the mitral valve position in a superior and medial direction towards the base of the heart. It traverses the chest wall (CW), right ventricular outflow tract (RVOT), anterior aortic wall (aAo), posterior aortic wall (pAo), left atrial cavity (LA) and left atrial posterior wall (LAPW).

#### Area 2.

This area is recorded by directing the transducer slightly inferiorly and laterally from area 1. This sound beam traverses the intraventricular septum (IVS), left ventricular outflow tract (LVOT) and anterior mitral valve leaflets (aML). Particular attention should be paid to the septal-aortic continuity.

#### Area 3.

This area is visualized by further tilting the transducer from direction 2 to direction 3, causing a sound beam to traverse the right and left ventricular cavity (RV and LV), posterior mitral leaflet (pML) and left ventricular posterior wall (LVPW).

#### Area 4.

This area is obtained by angling the transducer still further inferiorly and laterally towards the apex. The sound beam now passes the right and left ventricular cavity (RV and LV), intraventricular septum (IVS) and left ventricular posterior wall (LVPW).

This M-mode scan is of importance both with respect to anatomical information and transducer position during the recording. In the present study, M-mode recordings of area 3 were made for measurement of the transverse diameter of the left and right ventricle (LV and RV) and thickness of the intraventricular septum (IVS) both during the end-diastolic and end-systolic phase of the cardiac cycle.

### 3.1.3 Comparison of the antenatal and neonatal recording technique

Comparison of antenatal and neonatal recording data is only permitted if M-mode recordings have been made through the same cross-section of the heart. Care has been taken that the beam orientation through the heart was approximately equal. In the antenatal period a scan was made along a plane through the longitudinal axis of the heart as described in Paragraph 3.1.1, allowing visualization of five landmarks: left ventricular posterior wall (LVPW), intraventricular septum (IVS), right ventricular anterior wall (RVAW), mitral valve (MV) and aortic root (Ao). The same procedure was carried out during the neonatal period. An M-mode scan was made along a plane running through the longitudinal axis of the heart as described in Paragraph 3.1.2, resulting in the same landmarks as observed in the antenatal scan, justifying comparison of both scans.

### 3.2 Analysis of fetal and neonatal M-mode recordings.

In both fetal and neonatal M-mode recordings a number of variables were measured with the objective of gathering information on cardiac geometry and function during the antenatal and neonatal period. The results of this study will be presented in Chapters 5 and 6. The following variables were measured, using an X-Y digitizer (Paragraph 2.5):

- The transverse axis in mm of the left ( $D_{LV}$ ) and right ( $D_{RV}$ ) ventricle in the end-diastolic (ED) and end-systolic (ES) phase of the cardiac cycle. The transverse axis of the left ventricle (LV) runs from the endocardial surface of the left ventricular posterior wall (LVPW) to the endocardial surface of the intraventricular septum (IVS). The transverse axis of the right ventricle (RV) runs from the endocardial surface of the right ventricular anterior wall (RVAW) to the endocardial surface of the intraventricular septum (IVS).

The end-diastolic phase (ED) of the cardiac cycle was determined by the beginning, and the end-systolic phase (ES) by the maximum of the inward movement of the endocardial surface of the ventricular walls.

- The thickness in mm of the intraventricular septum ( $T_{VS}$ ) in the end-diastolic and end-systolic phase of the cardiac cycle.
- The beat-to-beat interval in msec. as expressed by the time interval between the end-systolic phase of two consecutive cycles. It was realized that measurement of beat-to-beat interval without an abdominal ECG was subject to some inaccuracy. Initial attempts to obtain simultaneous fetal M-mode and ECG recordings were unsuccessful for one or more of the following reasons:
  - . frequent manipulations of the large-size linear array real-time transducer on the maternal abdomen, thereby touching the ECG-electrodes;
  - . fetal movements.

It was therefore decided for calculation of the beat-to-beat interval, to measure the distance between the end-systolic phase of the consecutive cardiac cycles to the nearest 0.5 mm corresponding with a time interval of 25 msec. (10 mm = 500 msec, see Paragraph 2.5). As will be shown in Paragraph 3.3 this resulted in an acceptable reproducibility of this particular measurement.

### 3.3 Accuracy and reproducibility of M-mode measurement

In general terms the errors which are inherent in a measurement may be divided into two groups, systematic and random. Systematic errors give a measure of the difference between the measurements and the corresponding real values. Random errors give a measure of the reproducibility of the technique.

### 3.3.1 Systematic errors

The systematic error can be divided into the error of the instrumentation and the error caused by the finite beam width of the ultrasound wave. The error of the instrumentation can be considered as very small. The markers on the M-mode recording are generated by a highly stable oscillator, with an accuracy well below 0.1%. The sawtooth generator, which gives the vertical deflection on the M-mode recorder, has a linearity better than 1%. Moreover this generator writes the echo information with the markers, which means that the resulting error is even less. The system is calibrated at an ultrasound velocity of  $1540 \text{ m sec}^{-1}$  to generate the 1 cm intervals on the M-mode tracing. This coincides with the velocity through blood (Wells, 1977). Since a differential measurement is taken (i.e. between two points of the fetal heart), no errors will be introduced by the other structures positioned between the transducer and the fetal heart, which may show a different ultrasound velocity. In conclusion it is reasonable to assume that the errors due to instrumentation are well below 1%.

As outlined in Chapter 2, the ultrasound beam is not needle-shaped but shows a well-defined pattern. In particular, the finite beam width of the transducer may give ambiguous results for the exact position of a reflector. Fig. 3.8 shows schematically a cavity with the beam profile from a transducer. As can be observed, the measured diameter is always shorter than the real diameter. This has been confirmed in the literature (Kececioglu-Draeos et al, 1982; Barrett et al, 1982). To assess the error caused by the finite beam width one must be aware of the beam profile of the transducer used during the examination. Moreover the exact definition of the beam width must be established, since the strength of the ultrasound field diminishes gradually in a plane perpendicular to the transducer.

Fig. 3.8 Schematic representation of a cavity with the beam profile from a transducer.

Fig. 3.9 shows a computer simulation of an ultrasound field from a particular transducer. White represents the highest intensity of the ultrasound field, black is zero intensity. From this simulation it can be observed that maximum intensity is present on the main axis. This is called the main lobe. From the main axis the field diminishes and becomes zero. Further away from the main axis other maxima can be observed, the so-called side lobes of the ultrasound field. In practice it must be realized that by applying more amplification, the weaker off-axis echoes may also be registered. Care was taken during the investigation to minimize time gain amplification.

Fig. 3.9 A computer simulation of an ultrasound field. White is maximum intensity, black is zero intensity. Calculated sound intensity showing beam pattern of a focussed (at 6 cm) disc-shaped 3.12 MHz transducer. Total depth is 16 cm.

A well-accepted definition for the beam width of the transducer is the distance between two points in a plane perpendicular to the transducer, symmetrically positioned to the main axis, where the ultrasound power is half of its maximum. This figure, which of course may be depth dependent, is specified by all manufacturers of ultrasound equipment. However, it is questionable if these figures can be used to estimate the errors as is indicated by Figure 3.8. For example: using a beam width of a dynamically focussed system of 3 mm, the error still caused an underestimation of all measurements. This error was 4.6% at 10 mm diameter, 3% at 15 mm diameter and 2.3% at 20 mm diameter; and 13.2%, 8.7% and 6.7% respectively in volume measurements. The echoes generated at the edges of the ultrasound field may not be registered. Furthermore these echoes are reflected not perpendicular, but in a direction away from the transducer. An approach to establish the error caused by the finite beam width would be to use measurements from a fetal heart in a watertank. The latter should be done using a fresh fetal heart, not older than four hours post mortem (S. Goldberg, personal communication). This, however, is impractical. In addition an unrealistic time gain compensation would have to be introduced in these experiments, which would make the results disputable. As mentioned before, as described in the literature (Kececioglu-Draeos et al, 1982; Barrett et al, 1982), the measured diameter is always shorter than the real diameter. In these studies contours were obtained from apical views. This means that the entire contour measurements are influenced by curvature as well as by lateral resolution. This method was shown to yield an error between 10% and 20%. As a model the calculations of volume and surface derived from a single (M-mode) dimension may be less accurate compared to a contour derivation. However, the ultrasound volume estimation based on single measurements is, as far as ultrasound errors are concerned probably more accurate.

### 3.3.2 Random errors

Random errors may arise from:

- positioning of the transducer. The correct position of the transducer is solely determined by the definition of certain structures within the measuring object, i.e. the specific image characteristics as described in Paragraph 3.1. There will, however, always be a difference between the adopted and ideal transducer position. The resulting error can be assessed by repeating the measurement several times.
- movement of structures. Real-time systems allow visualization of moving structures. The potential error arising from transducer positioning may therefore become even larger, since movement of the measured object may be translated into a re-positioning of the transducer.
- the investigator. The reproducibility of the measurement is also determined by the care and patience of the investigator when carrying out the measurement.

### 3.3.3 Reproducibility of the antenatal measurements

#### a. Interobserver variation

Two different investigators, independently, measured the following parameters in ten consecutive fetal cardiac cycles from patients chosen at random between 28 and 41 weeks of gestation: the transverse diameter of the right and left ventricle ( $D_{rv}$  and  $D_{lv}$ ), thickness of the intraventricular septum ( $T_{vs}$ ) in the end-diastolic (ED) and end-systolic (ES) phase of the cardiac cycle in mm, and beat-to-beat interval in msec. First the mean of each of the parameters derived from 10 cardiac cycles was calculated for each patient. From these mean values the root of the pooled variance was subsequently calculated for all 10 patients together, using the formula

$$\sqrt{\frac{1}{n} \sum_k S_k^2} \quad , \quad n = \text{number of patients}, \quad S_k = \text{standard}$$

deviation for patient no. k, calculated from the two measurements (one from each investigator) for this particular patient. The results are presented in Table 3.1.

b. Intraobserver variation

In 10 consecutive fetal cardiac cycles from 10 patients chosen at random between 28 and 41 weeks of gestation, the same parameters as mentioned in Paragraph 3.3.3a were measured twice at an interval of several days by one investigator. The results of the root of the pooled variance of the parameters are presented in Table 3.1.

c. Inpatient variation

With an interval of 20 minutes two periods of 10 consecutive fetal cardiac cycles from 10 patients randomly chosen were measured by one investigator (Table 3.1).

d. Interpatient variation

Ten patients randomly chosen with a similar pregnancy duration (33 weeks) were included. In each patient 10 consecutive fetal cardiac cycles were studied and a mean of the parameters presented in Paragraph 3.3.3a was calculated. From these values the mean and standard deviation for all 10 patients together was established. This standard deviation, which is a measure of the interpatient variation, is presented in Table 3.1.

### 3.3.4 Reproducibility of the neonatal measurements

The method of calculating the intra- and interobserver variation, as well as the intra- and interpatient variation in the neonatal period was similar to that described in Paragraph 3.3.3. The intra- and interobserver variation as well as the inpatient variation were calculated for the same parameters as defined in Paragraph 3.3.3a in 10 infants chosen at random, from 10 min before delivery till 48 hours following delivery. The interpatient variation was determined in 10 infants on the 2nd day post partum. The results are given in Table 3.2.

	LV		RV		IVS		beat-to-beat
	ED	ES	ED	ES	ED	ES	interval
interobserver variation	0.39	0.35	0.60	0.49	0.13	0.09	0.07
intraobserver variation	0.02	0.06	0.04	0.04	0.03	0.06	0.06
inpatient variation	0.05	0.03	0.05	0.04	0.05	0.05	0.06
interpatient variation	1.44	1.10	1.39	1.12	0.28	0.29	0.35

Tabel 3.1 Reproducibility of the measurements during the antenatal period.

This table presents the root of the pooled variance as a measure for the interobserver variation, intraobserver variation and inpatient variation calculated for the LV and RV diameters in the ED and ES phase, the thickness of the IVS in the ED and ES phase, and beat-to-beat interval. The standard deviation is a measure for the interpatient variation expressed as twice the mean values of the above-mentioned parameters.

	LV		RV		IVS		beat-to-beat
	ED	ES	ED	ES	ED	ES	interval
interobserver variation	0.14	0.19	0.10	0.14	0.09	0.07	0.08
intraobserver variation	0.06	0.05	0.04	0.03	0.05	0.07	0.07
inpatient variation	0.11	0.07	0.08	0.09	0.13	0.05	0.11
interpatient variation	0.55	0.54	0.37	0.31	0.59	0.72	0.32

Table 3.2 Reproducibility of the measurements in the neonatal period.

This table presents the root of the pooled variance as a measure for the interobserver variation, intraobserver variation and inpatient variation calculated for the LV and RV diameters in the ED and ES phase, the thickness of the IVS in the ED and ES phase, and beat-to-beat interval. The standard deviation is a measure for the interpatient variation expressed as twice the mean values of the above-mentioned parameters.

Both in the antenatal and neonatal period the root of the pooled variance calculated for the interobserver variation, intraobserver variation and inpatient variation is considerably smaller than the standard deviation established for the interpatient variation. Since the systemic error is of minor importance only, it can be concluded from these data that the M-mode measurements as described in this Chapter are sufficiently accurate and reproducible to characterize each patient.

### 3.4 Discussion

In the child and the adult, M-mode echocardiography has rapidly achieved popularity as a non-invasive technique for obtaining quantitated dimensional measurements of cardiac chamber size, wall thickness, wall motion velocities, great vessel dimensions and valve motion (Pombo et al, 1970; Feigenbaum, 1972; Epstein et al, 1975; Sahn et al, 1978). Edler and Hertz (1954) were the first to establish motion patterns of fetal cardiac structures. Murata et al (1971) pointed out that information such as the shape of cardiac motion curves, the depth of a moving structure from the surface, relative velocity of motion, the heart rate and phase relationship could be collected from M-mode recordings. He also used other parameters, such as the fetal electrocardiogram (ECG), phonocardiogram and Doppler signals. More detailed descriptions of motility patterns of fetal intracardiac structures became available through the work by Egeblad et al (1975). They primarily scanned the heart by B-mode and subsequently obtained motility patterns of the cardiac structures and diameters by means of M-mode recording. Movements of the aortic and pulmonary root as well as atrioventricular valves were recorded relative to the systolic and diastolic phase of the cardiac cycle. During the last 5 years marked improvement in two-dimensional real-time imaging has resulted in even more detailed and accurate M-mode data on

fetal and neonatal cardiac structures. Ianniruberto et al (1977) analysed mitral valve opening and closure times. It was Hobbins et al (1978) and later both our own laboratory (Wladimiroff et al, 1979; Vosters et al, 1979; Wladimiroff et al, 1980; Wladimiroff and McGhie, 1981b) and Allan et al (1982) in London, which established M-mode data on left and right ventricular chamber size in the term fetus. Lately, M-mode echocardiography has shown to be useful in the prenatal diagnosis of congenital heart disease and cardiac dysrhythmias. Baars et al (1977) published a case of fetal paroxysmal tachycardia at term. Kleinman et al (1978) diagnosed a complete atrioventricular block on the basis of an abnormality of mitral valve and left ventricular posterior wall motion at 28 weeks of gestation and in a second fetus an atrial flutter at 38 weeks of gestation.

In this chapter we presented the technique of obtaining a satisfactory M-mode recording during both the fetal and neonatal period. We opted for the long-axis view of the cardiac ventricles as a standard plane for M-mode echocardiography. Sahn et al (1980) obtained fetal and newborn cardiac measurements from two-dimensional views showing the four cardiac chambers. Their preference for this particular view was based on work by Bommer et al (1979), who suggested that measurement of the right ventricle on four chamber apical views at the level just below the tricuspid valve correlates closely with the maximum right ventricular short axis dimensions measured from anatomical casts. It is, however, not possible to obtain an M-mode recording of both cardiac ventricles at right angles to the intraventricular septum from this particular cross-section. With regard to the level of the ventricles at which to measure the transverse dimensions on a long-axis view, we recorded at the level of the mitral valve leaflets. This position was recommended for ventricular measurements in examinations of small hearts by the Committee on M-mode standardization of the American Society of Echocardiography (Sahn et al, 1978).

Up until now only Sahn et al (1980) in their two-dimensional study and Wladimiroff et al (1980) in their M-mode cardiac study have examined the reproducibility of their measurements. As previously mentioned one of the factors which affects the accuracy of echocardiographic measurements, is the clarity of the interface delineation. This applies in particular to the visualization of the endocardial echo on either side of the intraventricular septum and endocardial echo of the right ventricular anterior wall and left ventricular posterior wall. The endocardial echo is less intense than the epicardial-pericardial complex and lies very close to a cluster of intraventricular echoes which probably arise from the posterior chordae (Popp and Harrison, 1970).

This problem of identifying boundaries of a structure because of poor quality, either secondary to instrumentation or to mid-anterior position of the fetal spine, excessive movements or maternal obesity was the main reason for rejecting a number of M-mode recordings, as will be discussed in Chapter 4.

In our own study we did not follow the classic method of millimeter ruler and callipers, but used a light-pen X-Y digitizer, as described in Paragraph 2.5, for the various cardiac measurements. This system has an accuracy of  $\pm 0.08\%$ . Nonetheless, the greatest measurement problem is not in the actual determination of the distance between two points, but in the process of determining between which points the distance should be measured. Despite the fact we were not in possession of a simultaneous fetal ECG-recording for a more accurate estimation of the end-diastolic and end-systolic phase of the cardiac cycle, the figures on intra- and inter-observer variation of the left and right ventricular transverse dimension, septal thickness and beat-to-beat interval showed an acceptable reproducibility of these measurements both in the antenatal and early neonatal period.

## Chapter 4

### PATIENT SELECTION AND STATISTICAL TESTS IN THE PRESENT STUDY

The cardiac M-mode recordings in the present study were obtained in the Department of Obstetrics and Gynaecology of the Academic Hospital Rotterdam - Dijkzigt between June 1978 and January 1981.

#### 4.1 Uncomplicated pregnancy

Data were derived from 246 randomly selected subjects with an uncomplicated pregnancy between 28 and 41 weeks of gestation. All women were of caucasian origin and all gave consent to participate in the study.

##### 4.1.1 Selection procedure.

Pregnancy was considered uncomplicated if the following conditions were met:

- a. maternal age between 20 and 30 years;
- b. a regular menstrual cycle; known date of last menstrual period; confirmation of calculated gestational age from either a single fetal crown-rump length measurement between 7 and 12 weeks or a single measurement of the fetal biparietal diameter (BPD) between 13 and 22 weeks of gestation;
- c. presence of a single fetus;
- d. uneventful antenatal period and delivery:
  - normal fetal growth, as established by clinical and ultrasound examination;
  - spontaneous delivery after a pregnancy duration of at least 37 weeks;
  - birth weight between 10th and 90th percentile for

weight of gestation according to the Tables of Kloosterman (1970), corrections being made for maternal parity and fetal sex;

- Apgar score at 1 minute 8 or more;
- no congenital abnormalities.

The study of cardiac geometry and function consisted of two parts:

- a cross-sectional antenatal study between 28 and 41 weeks of gestation in 193 out of 246 normal subjects, i.e. a rejection rate of 22%. The various reasons for failing to obtain an acceptable cardiac M-mode recording have been discussed in Chapter 3.
- a longitudinal antenatal-early neonatal study in 15 out of 18 normal subjects (rejection rate 17%). In this group of 15 women it was possible to obtain an M-mode recording of the fetal heart within 12 hours of delivery, since labour was induced for elective reasons immediately following the ultrasound scan. Induction of labour was carried out by means of amniotomy and intravenous Oxytocin drip and was always followed by a spontaneous delivery 2 to 8 hours later. If necessary analgesics were administered to a maximum of two doses of 50 to 75 mg of Pethidin i.m. A second cardiac M-mode recording was carried out within 10 minutes following delivery and a further 3 recordings at 4 hours, 24 hours and 48 hours respectively. These serial measurements allowed comparison of antenatal cardiac findings with those obtained during the first 48 hours following delivery.

#### 4.1.2 Statistical tests

All cross-sectional antenatal data were related to gestational age. If a linear change in a particular cardiac parameter was observed, its significance was examined by means of the Pearson product-moment correlation test. In cases with significant change, the expected mean value based on the linear regression

line was presented for each week of gestation. In cases with no significant change, all antenatal values of that particular cardiac parameter were lumped together and the mean  $\pm$  1 SD calculated. If a curvilinear change was noted, the mean value for each week of gestation was given. Statistical significance was subsequently assessed by means of the Wilcoxon non-paired rank test.

All data from the longitudinal antenatal-neonatal study were related to the five periods described in section 4.1.1 and the mean value for each period was calculated. The significance of any change between these periods was examined by means of the Wilcoxon matched-pair signed rank test.

#### 4.2 Complicated pregnancy

A total of 25 pregnant women with fetal growth retardation were studied. The selection procedure for these patients was similar to that described in paragraphs 4.1.1a, b and c. A technically acceptable M-mode recording was collected in 19 out of 25 subjects (rejection rate 24%). Results will be presented in Chapter 7.

Fetal growth retardation was suspected when there was a negative discrepancy of 2 weeks or more between the uterine fundal height and gestational age during two successive antenatal check-ups. Subsequent confirmation of a retardation of fetal growth was obtained from ultrasonic measurements of fetal head and chest size. Fetal head size was established by means of measurement of the fetal biparietal diameter (BPD) and fetal chest size as expressed by the transverse chest area (Wladimiroff et al, 1978). Both fetal BPD and chest area were situated on or below the lower limit (5th percentile) of the normal curves according to Wladimiroff et al (1978). Birth weights were classified in 3 categories: between the 5th and 10th percentile, between 2.3rd and 5th

percentile, and below the 2.3rd percentile according to the Tables of Kloosterman (1970), corrections being made for maternal parity and fetal sex.

## Chapter 5

### NORMAL VENTRICULAR GEOMETRY DURING THE LAST TRIMESTER OF PREGNANCY AND EARLY NEONATAL PERIOD

In this chapter the results from our own study on fetal and neonatal ventricular geometry will be presented.

#### 5.1 Left and right ventricular transverse diameter

( $D_{lv}$  and  $D_{rv}$ )

Figs. 5.1 and 5.2 demonstrate the data distribution of the transverse diameter of the left ventricle in the end-diastolic (ED) and end-systolic (ES) phase of the cardiac cycle against gestational age, and the linear regression line. There is a linear increase in the transverse diameter of the left ventricle both in the end-diastolic (ED) ( $p < 0.001$ ) and end-systolic (ES) phase ( $p < 0.001$ ) of the cardiac cycle. The slope of the regression line is  $0.49 \text{ mm wk}^{-1}$  in the end-diastolic (ED) and  $0.44 \text{ mm wk}^{-1}$  in the end-systolic (ES) phase.

Figs. 5.3 and 5.4 show the transverse diameter of the right ventricle in the end-diastolic (ED) and end-systolic (ES) phase of the cardiac cycle. Here also, a linear increase in the transverse diameter can be observed (ED:  $p < 0.001$ ; ES:  $p < 0.001$ ). The slope of the regression line is  $0.49 \text{ mm wk}^{-1}$  in the end-diastolic (ED) and  $0.44 \text{ mm wk}^{-1}$  in the end-systolic (ES) phase. The ratio between the right and left ventricular transverse diameter ( $\frac{D_{rv}}{D_{lv}}$ ) at corresponding moments in the cardiac cycle was related to age.

No significant change in ratio was observed between 28 and 41 weeks of gestation (Figs. 5.5 and 5.6). For the entire antenatal study period the mean right-to-left ventricular ratio was  $1.00 \pm 0.04$  during end-diastole (ED) and

1.00  $\pm$  0.04 during end-systole (ES).

Figs. 5.7 and 5.8 represent the data distribution and mean values of the transverse diameter of the left ventricle during end-diastole (ED) and end-systole (ES) within 12 hours before and 10 minutes, 4 hours, 24 and 48 hours following delivery. A significant increase ( $p < 0.01$ ) in transverse diameter during end-diastole (ED) from 17.7 to 19.2 mm could be observed within 10 minutes following delivery; this was followed by a fairly constant pattern during the remainder of the study period. The increase in transverse diameter immediately following delivery, was also significant during end-systole (ES) ( $p=0.02$ ), i.e. from 14.1 to 15.0 mm. However, from this moment no further changes occurred. The transverse diameter of the right ventricle (Figs. 5.9 and 5.10) demonstrated a highly significant reduction in size immediately following delivery from 17.7 to 10.5 mm during end-diastole (ED) ( $p < 0.01$ ) and from 14.3 to 8.8 mm during end-systole (ES) ( $p < 0.01$ ). During the remainder of the study period the transverse diameter stayed virtually unaltered. The right-to-left ventricular ratio (Figs. 5.11 and 5.12) underwent a significant reduction within 10 minutes following delivery from 1.00 to 0.55 during end-diastole (ED) ( $p < 0.01$ ) and from 1.00 to 0.59 during end-systole (ES) ( $p < 0.01$ ). This reduction continued till 4 hours following delivery.

#### 5.1.1 Discussion

Up until 10 years ago, published data on fetal heart size were restricted to measurements obtained from autopsies. Garrett and Robinson (1970) were the first to measure heart size in live fetuses using a compound-B scanner. They showed the greatest transverse diameter of the heart to be about 50% of the corresponding diameter of the chest. There was no difference in growth between the fetal heart and chest in the last 8 weeks of pregnancy. The heart occupies 21% of the

cross-sectional area of the chest. Later, Suzuki et al (1974), using a compound-B scanner, established fetal total cardiac volume during the last trimester of pregnancy, whereby it was assumed that the configuration of the heart approaches a prolate ellipse. Values from 20 to 60 ml were found. Only a limited number of reports is available on cardiac ventricular geometry in the human fetus and early neonate. The published data were either obtained from a compound-B scanner, a two-dimensional real-time system or from T-M recordings. Comparison of the results derived from these three different methods is difficult, particularly since the first scanning technique must be considered less accurate with regard to the delineation of the endocardial lining of both ventricles and the definition of the end-diastolic and end-systolic phase of the cardiac cycle. The low success rate in the studies by Garrett and Robinson (1970) and Winsberg (1972) is understandable in the light of the less-developed equipment available at that time (Table 5.1). However, even in a more sophisticated set-up as has been employed in our own study, an antenatal success rate of only 67% (Wladimiroff et al, 1979) and 78% (present study) had to be accepted. The success rate of 72% in Sahn's study (1980) is partly based on the fact that when the fetal lie was unsatisfactory, the mother was often asked to return at a later time, at which time the examination was successfully completed. When looking at the actual figures for the left ventricular transverse diameter as produced by the various investigators, again problems arise. Whereas Winsberg (1972), Allan et al (1982) and ourselves (Wladimiroff et al, 1979; present study) have carried out measurements from long-axis views of the fetal heart at the level of the mitral valve leaflets, Sahn et al (1980), as well as Garrett and Robinson (1970), studied left and right ventricular geometry from 4-chamber views. In neither study a difference between the end-diastolic and end-systolic phase of the cardiac cycle was made, although Sahn had carried out all his measurements on a real-time scanner. It is not surprising that with differences in equipment, scanning planes and periods of

pregnancy during which the measurements were made the results have been variable.

Both transverse and longitudinal axis measurements on the fetal left and right ventricle have also been performed in the fetal lamb. Kirkpatrick et al (1973) using ultrasound in a chronically instrumented lamb at term measured a left ventricular transverse diameter of  $12.5 \pm 0.3$  mm (1 SEM) in end-diastole (ED) and  $9.5 \pm 0.4$  mm (1 SEM) in end-systole (ES). These values are much smaller than those found by ourselves in the human fetus. This is probably largely due to the fact that in the lamb experiment the ultrasonic crystals were not placed perpendicular to the longitudinal axis of the left ventricle but in the sulcus just posterior to the papillary muscle, across a chord rather than at the true maximum internal diameter. There are also a number of anatomical studies on the fetal left-to-right ventricular relationship available. Spigelius (1626) and Harvey (1628) in the 17th chapter of the *Motis Cordis* recognized that in the human fetus and newborn the left and right ventricular wall are of approximately equal thickness. During the last century, however, some doubts have arisen as to their exact equality. These doubts could be mainly ascribed to the work by Müller (1883), although later it appeared that there were serious flaws in the selection of material and methods used in this particular study. From more recent work it seems that the two ventricles are of equal thickness in mid-gestation, but that there is a slight right ventricular preponderance at term (Hort, 1955, 1966; Emery and MacDonald, 1960; Recavarren and Arias-Stella, 1964). Emery and Mithal (1961) reported a mean weight of the left ventricle at birth of  $5.7 \pm 1.1$  gr (1 SD) and of the right ventricle  $6.3 \pm 1.4$  gr (1 SD). Keen (1955) and Hort (1966) used only the free walls of the ventricles. Keen concluded that both ventricles were of approximate equality at term, whereas Hort found the left ventricle to be smaller. The difference was ascribed to a difference in the plane of sections. Hort also concluded

that at birth the external surface of the right ventricular wall was larger than the left.

Ventricular weights were also studied in the lamb and pig. The advantage here is that in contrast to the human fetus which had usually died from progressive asphyxia, freshly killed animal fetuses could be studied. Both in the fetal lamb (Dawes, Mott and Widdicombe, 1954; Romero, Covell and Friedman, 1972) and in the pig (Yuan, Heymann and Rudolph, 1966) no significant difference in left and right ventricular weight could be established. Dawes (1969) suggested that either there is a species difference or the ventricular inequality in man at birth is determined by the mode of death or the method used to weigh the ventricles.

From Table 5.2 it can be seen that during the early neonatal period only limited data on cardiac geometry are available. The success rate in obtaining a particular cardiac plane for geometric measurements was low, not only by using a compound-B scanner (Winsberg, 1972) but also by using a real-time method (Sahn et al, 1980). The recording failures in the study by Wladimiroff et al (1980) and in the present work were always due to problems in the antenatal measurement. Since these were longitudinal studies, failure to obtain a satisfactory antenatal recording resulted in dropping the patient from the neonatal follow-up altogether. For reasons similar to those pointed-out in the discussion on the antenatal data in Table 5.1, comparison of results from different investigators is difficult. Although reasonable agreement exists on left ventricular transverse diameter during the end-diastolic (ED) phase of the cardiac cycle as reported by Winsberg (1972), Wladimiroff et al (1980) and ourselves, left ventricular transverse diameter during the end-systolic (ES) phase in the present study is significantly larger than that observed by Winsberg. There is also a substantial difference in right-to-left ventricular ratio as obtained by Sahn et al (1980) and ourselves. The marked reduction in neonatal right ventricular

transverse diameter (69% in end-diastole (ED) and 63% in end-systole (ES)) and therefore in right-to-left ventricular ratio is in agreement with findings in the neonatal pig in which the right ventricle adopts a more shell-shaped size, whereas the left ventricle retains its original balloon-like shape (Harinck, 1974; Versprille et al, 1977). These animal experimental data suggested that the observed reduction in right ventricular transverse diameter is caused by functional geometric changes induced by loading one side of the heart following clamping of the cord and subsequent lung expansion. In contrast to the pronounced change in right ventricular transverse diameter, the left ventricular transverse diameter soon after birth exhibits only a slight increase of 9% in end-diastole (ED) and 8% in end-systole (ES) as a result of the rise in aortic pressure. Serial sonocardiometric measurements in the lamb from late term through birth demonstrated an initial increase of  $\pm$  8% in left ventricular transverse diameter as the chest was delivered and a further increase of  $\pm$  5% with the onset of pulmonary ventilation (Kirkpatrick et al, 1973). These figures are close to the 8-9% calculated in our own study. The constancy of the left and right ventricular transverse diameter values during the remainder of the neonatal study period underlines the very short period following delivery during which the changes in left and right ventricular size take place.

Anatomical studies on human neonatal hearts have shown that after birth the left ventricular wall grows rapidly while the right does not. The free wall of the right ventricle has even been found to be reduced in weight by 20% over the first month after birth (Keen, 1955; Hort, 1955). Emery and Mithal (1961), however, pointed out that the left ventricular weight preponderance which they established by the end of the 4th week of life is not due to atrophy of the right ventricle, but is the product of difference in growth. Left ventricular preponderance was established at an even earlier stage in the neonatal lamb (Romero et al, 1972): at 7-14 days following

delivery the free wall of the right ventricle was reported to be about 25% heavier than that of the fetal right ventricle, whereas the free wall of the left ventricle had almost doubled in weight.

## 5.2 Left ventricular volume ( $Q_{1V}$ )

Wladimiroff and McGhie (1981a) developed a method for estimating left ventricular volume from two-dimensional real-time ultrasonic images. The scanning plane through the long-axis of the fetal heart was identical to that used for the M-mode studies (Paragraph 3.1.1). The dynamics of the largest longitudinal cross-section through the left ventricle was recorded on video tape during 10 to 15 cardiac cycles. Based on a fetal heart rate between 120 and 150 beats per minute which corresponds with a beat-to-beat interval between 400 and 500 milliseconds and an image repetition frequency of the video-display of 20 milliseconds, 25 consecutive still frames within one cardiac cycle were studied for establishing the end-diastolic (ED) and end-systolic (ES) phase of the left ventricle. In the final step the transverse and the longitudinal axis of the left ventricle were measured by means of a computer-linked light pen system. The transverse axis was measured at the level of the mitral valve leaflets and ran from the endocardial surface of the intraventricular septum to the endocardial surface of the left ventricular posterior wall. The longitudinal axis ran from the base of the aortic root to the endocardial surface of the left ventricular apex. The end-diastolic (ED) phase of the cardiac cycle was determined by the largest, the end-systolic (ES) phase by the smallest measurement of this particular axis. The longitudinal axis of the right ventricle could not be obtained since the pulmonary trunk does not show in this particular scanning plane. In each subject, three consecutive cardiac cycles of acceptable technical quality were studied this way and the mean value for the transverse and

longitudinal axis of the left ventricle in the end-diastolic (ED) and end-systolic (ES) position calculated. The measuring error in 95% of the recordings studied was, in the transverse axis 4.9% or less in the end-diastolic (ED), and 4.7% or less in the end-systolic (ES) position. For the longitudinal axis it was 4.0% or less in the end-diastolic (ED) and 4.1% or less in the end-systolic (ES) position.

Based on the assumption that the antero-posterior axis of the left ventricle, which cannot be measured, is equal to the transverse axis and the shape of the left ventricle is approaching a prolate ellipsoid, an estimation of left ventricular volume ( $Q_{1V}$ ) can be made, using the following formula (Ten Cate et al, 1974):

$$Q_{1V} \text{ (ml)} = \frac{\pi}{6} \times \text{transverse axis}^2 \times \text{longitudinal axis}$$

The results showed that in the 3rd trimester of pregnancy the longitudinal-to-transverse axis ratio of the left ventricle is  $1.75 \pm 0.1$  (1 SD) during the end-diastolic (ED) phase and  $1.90 \pm 0.1$  (1 SD) during the end-systolic (ES) phase of the cardiac cycle. A separate study carried out on 10 infants during the first two days after birth showed an unaltered relationship between the two diameters. This is in agreement with the finding that the shape of the left ventricle does not change significantly during this period of early neonatal life. From the above-mentioned it was decided to multiply the transverse diameter of the fetal and neonatal left ventricle measured from M-mode recordings by 1.75 during end-diastole (ED) and by 1.90 during end-systole (ES) in order to obtain an estimate of the longitudinal axis of the left ventricle.

Antenatally there is a curvilinear increase in left ventricular volume ( $Q_{1V}$ ) both during the end-diastolic ( $Q_{1ved}$ ) (Fig. 5.13) and end-systolic ( $Q_{1ves}$ ) phase (Fig. 5.14) of the cardiac cycle. Due to this curvilinear increase in volume,

the mean values for  $Q_{lved}$  and  $Q_{lves}$  were calculated for each week of gestation.  $Q_{lved}$  rose from 1.5 ml and  $Q_{lves}$  from 0.7 ml at 28 weeks to 5.6 ml and 2.8 ml respectively at 40 weeks of gestation ( $p < 0.001$ ). During the first 10 minutes following delivery a further rise in  $Q_{lved}$  from 5.5 ml to 6.6 ml;  $p < 0.01$  (Fig. 5.15) and  $Q_{lves}$  from 2.7 to 3.2 ml;  $p = 0.05$  (Fig. 5.16) was noted. During the remainder of the neonatal period no significant change in  $Q_{lv}$  occurred.

### 5.2.1 Discussion

Assessment of volume was restricted to the left ventricle, since no information could be obtained on the longitudinal axis of the right ventricle on the same long-axis plane. For the calculation of left ventricular volume during the end-diastolic and end-systolic phase of the cardiac cycle, assumptions were made for the shape of the left ventricle as well as for the relationship between the transverse and antero-posterior diameter of the ventricle. The theoretical basis for the prolate ellipsoid shape of the left ventricle was originally derived from angiographic studies in the adult (Dodge et al, 1960; Davila and Sanmarco, 1966; Hermann and Bartle, 1968). Later studies of our own based on human fetal autopsy specimens support this approach. It is clear that, based on the previous assumption that the antero-posterior axis of the left ventricle is equal to the transverse axis and the shape is approaching a prolate ellipse, the values for left ventricular volume presented in the cross-sectional and longitudinal study should only be considered to be an approximation rather than a true representation of that ventricular volume. Verification of our data was not possible due to the absence of comparative studies in the literature.

### 5.3 Thickness of the intraventricular septum ( $T_{vs}$ )

Antenatally, the change in the intraventricular septal thickness depicted a linear increase, both in the end-diastolic (ED) ( $p < 0.001$ , Fig. 5.17) and end-systolic (ES) phase ( $p < 0.001$ , Fig. 5.18) of the cardiac cycle. During the first 4 hours following delivery, a further rise in thickness could be observed during end-systole (ES) (Fig. 5.19), i.e. within 10 minutes: from 2.6 to 3.8 mm ( $p < 0.01$ ); at 4 hours: from 3.8 to 4.4 mm ( $p < 0.01$ ). During end-diastole (ED) no significant changes occurred (Fig. 5.20).

#### 5.3.1 Discussion

From our data on intraventricular septal thickness it appears that during the antenatal period there is no significant difference in septal thickness between end-diastolic and end-systolic phase of the cardiac cycle. The increase in septal thickness from 28 weeks to 40 weeks of gestation was 33% (end-diastole, ED) and 32% (end-systole, ES) respectively. Comparable data on septal thickness are only available from two other studies. In one study carried-out in the human fetus (Allan et al, 1982) slightly higher septal thickness values were found. The number of observations between 28 and 40 weeks was, however, much smaller ( $n=42$ ) than that in our own study. In another study in fetal dogs (Williams et al, 1978) near term values of  $2.08 \pm 0.27$  mm (1 SD) at aortic valve level and  $2.83 \pm 0.40$  mm (1 SD) at mid-ventricular wall level were found. This implies that septal thickness varies considerably with respect to the level at which the measurement is carried out. Our septal thickness values at term of 2.6 mm in the end-diastolic phase and 2.5 mm in the end-systolic phase of the cardiac cycle are in reasonable agreement with those observed in dogs, since in our study the level of measurement is nearer to the mid-ventricular than the aortic valve level. Antenatal information on septal

development was also obtained from weight studies in the human fetus, in which the septum was either kept separate (Keen, 1955) or allotted between the left and right ventricle in proportion to their respective weight (Müller, 1883; Lewis, 1914; Herrmann and Wilson, 1922). Anatomical studies (Fulton et al, 1952; Keen, 1955) have shown that the septum in its increase follows the free wall of the left ventricle closely and is not influenced by the behaviour of the right ventricular free wall. Hislop and Reid (1972) also found that the septum grew with the left ventricle rather than with the right, supporting the two previous investigators. However, this does not mean that the septum, by its contraction, does not assist the right and left ventricle. From these studies it also appeared that the increase in intraventricular septal weight during the 3rd trimester of pregnancy is approximately 200-250%. At term the weight of the septum averaged about 18% of the total ventricular weight. In the neonatal period the intraventricular septal thickness showed a pronounced increase of 46% during the end-systolic phase, whereas no significant changes occurred during the end-diastolic phase of the cardiac cycle. The significance of these changes with respect to ventricular function will be discussed in Chapter 6.

#### 5.4 Summary

- A. Combined use of two-dimensional real-time and M-mode technique as described in Chapter 3 provides an acceptable M-mode recording of 3rd-trimester fetal and early neonatal ventricular transverse diameter and septal thickness in over three quarters of the subjects studied.
- B. During the 3rd trimester of pregnancy left and right ventricular transverse diameter were equal in size both during the end-diastolic and end-systolic phase of the cardiac cycle. They followed a linear growth pattern. Left ventricular volume followed a curvilinear growth profile resulting in an increase, which is approximately

4-fold; left ventricular volume during the end-diastolic phase of the cardiac cycle was about twice that during the end-systolic phase. The intraventricular septal thickness showed a linear increase of 33%. There was no difference in septal thickness between the end-diastolic and end-systolic phase of the cardiac cycle.

- C. Immediately following delivery left ventricular transverse diameter and volume were characterized by a slight further increase, whereas the right ventricular diameter underwent a marked reduction, caused by functional geometric changes induced by loading one side of the heart. During the remaining 48 hours no significant changes in ventricular size could be observed. The intraventricular septum showed a further pronounced dimensional increase of 46% during the end-systolic phase without any significant change during the end-diastolic phase of the cardiac cycle.

## Chapter 6

### NORMAL VENTRICULAR DYNAMICS DURING THE LAST TRIMESTER OF PREGNANCY AND EARLY NEONATAL PERIOD

As already has been explained in Chapter 3, in each patient the beat-to-beat interval was measured to the nearest 5 msec and a mean value over 10 consecutive cardiac cycles was subsequently calculated. Since the observed neonatal changes in right ventricular size, discussed in Chapter 5, are most likely geometrically determined, the neonatal cardiac functions, studied, were only derived from left ventricular data.

#### 6.1 Beat-to-beat interval

Fig. 6.1 represents the beat-to-beat interval for 193 normal pregnancies between 28 and 41 weeks of gestation. There was a wide distribution of the individual data and no relationship between this dynamic variable and gestational age. Postnatally there was a rise in beat-to-beat interval (Fig. 6.2) which became significant 4 hours following delivery ( $p < 0.05$ ). The remainder of the neonatal study period was characterized by a stable interval.

##### 6.1.1 Discussion

Beat-to-beat interval is influenced by conditions such as age, circadian rhythm, stress, hypoxia, drugs and a number of pregnancy-related diseases (i.e. diabetes mellitus, hypertension etc.). In our study a normal pregnant population was investigated. In the fetal study, mothers were always placed in supine position, during the afternoon between 2.00 and 5.00 hours, and no drugs were administered.

As already stated in Paragraph 4.1.1 birth weight was always between 10th and 90th percentile for weight of gestation according to the Tables of Kloosterman (1970) and the Apgar score at 1 minute was 8 or more. Visser et al (1981) observed a reduction in fetal heart rate between 24 and 40 weeks with a tendency to rise thereafter. We did not observe any significant change in beat-to-beat interval relative to gestational age. The variation in heart rate was always within the range of 3-15 beats  $\text{min}^{-1}$ , which means that no M-mode recordings were collected during an acceleration ( $>15$  beats  $\text{min}^{-1}$ ) or deceleration ( $>15$  beats  $\text{min}^{-1}$ ) of the fetal heart rate. During the first 10 minutes following delivery, a slight increase in beat-to-beat interval was noted. These findings disagree with those reported by Cordero (1972) and de Jong et al (1974), who observed an elevation of heart rate immediately following delivery. This difference may be explained by the fact that the recordings in our study were nearly always produced near the 10 minute time mark rather than the first few minutes following delivery. This would mean that we missed the increase in heart rate which apparently occurs in the first few minutes following birth. Mean beat-to-beat interval demonstrated a further rise to a maximum of 490 msec at 4 hours.

## 6.2 Left and right ventricular shortening ( $\Delta D_{lv}$ and $\Delta D_{rv}$ )

The shortening ( $\Delta D$ ) of the transverse diameter (D) of the left and right ventricle during systole is expressed by the following formula:

$$\Delta D \text{ (mm)} = D_{ed} - D_{es}$$

Antenatally (Figs. 6.3 and 6.4) there was a linear increase in  $\Delta D$  from 3.3 to 3.9 mm for the left ventricle ( $p < 0.001$ ) and from 3.3 to 4.0 mm for the right ventricle ( $p < 0.001$ ). The first 10 minute period following delivery is characterized

by a rise in left ventricular shortening ( $\Delta D_{lv}$ , Fig. 6.5) from 3.8 to 4.3 mm ( $p = 0.02$ ). As stated in the introduction of this chapter no functional data from the neonatal right ventricle were obtained.

### 6.2.1 Discussion

The antenatal rise in left and right ventricular shortening ( $\Delta D_{lv}$  and  $\Delta D_{rv}$ , Figs. 5.1-5.4) may reflect increasing circulatory demands associated with fetal growth. The data also indicate functional equality of both ventricles. The presence of an intrinsic relationship between resting (end-diastolic) fibre length and cardiac performance has been pointed out in several studies utilizing isolated cardiac muscle (Friedman, 1972), chick embryo (Faber et al, 1974) and acute intact fetal lamb models (Brinkman et al, 1965) or neonatal lamb models (Downing et al, 1965). In the adult animal and man, changes in extent of ventricular shortening and stroke volume as a result of changes in end-diastolic fibre length, i.e. the Frank-Starling mechanism (Frank, 1895; Starling, 1918) is well-established. In the fetus, however, some controversy existed as to the presence and importance of the Frank-Starling mechanism in the intact fetal heart. Rudolph and Heymann (1974) in chronically instrumented fetal lamb suggested that the Frank-Starling mechanism was of minor importance compared with the role of changing heart rate. Kirkpatrick et al (1976), however, pointed out that the fetuses in this particular study were operating close to the apex of their respective ventricular function curves since their end-diastolic pressures at rest were above the upper limit of the normal range (2.5-8 mmHg). Another criticism was the non-physiological way of changing fetal heart rate: bradycardia by vagal stimulation, tachycardia by atrial pacing. Kirkpatrick et al (1976) noted in their chronically instrumented fetal lambs during both spontaneous changes of heart rate and variations due to respiratory

efforts, changes in left ventricular end-diastolic diameter, which resulted in alterations of stroke volume that maintained a stable cardiac output. These data demonstrate that the Frank-Starling mechanism is effective in the fetal lamb. In our own antenatal study, the cross-sectional design did not allow us to examine the effect of fetal heart rate on left ventricular end-diastolic diameter. Moreover, all recordings were obtained during fetal apnoea. The increase in left ventricular ED-diameter following delivery was not accompanied by a change in beat-to-beat interval (Fig. 6.2). The increase in left ventricular ED-diameter and therefore of shortening, is rather, determined by circulatory alterations which following birth, impose on the left ventricle both an added volume and pressure load. With the onset of breathing pulmonary vascular resistance is markedly reduced (Dawes et al, 1953). Closure of the low-resistance placental circuit causes an increase in aortic pressure (Dawes et al, 1953) and closure of the ductus arteriosus is associated with a further rise in aortic pressure (Dawes et al, 1955). This would result in a reduction of stroke volume for a given left ventricular ED-diameter and pressure. Since blood flow to the left side of the heart will increase, this will result in a larger end-diastolic fibre length.

### 6.3 Left ventricular stroke volume ( $Q_{1vs}$ ), output ( $Q'_{lv}$ ) and ejection fraction ( $\frac{Q_{1vs}}{Q_{1ved}}$ )

#### 6.3.1 Left ventricular stroke volume ( $Q_{1vs}$ )

The difference between left ventricular volume in the end-diastolic ( $Q_{1ved}$ ) and end-systolic ( $Q_{1ves}$ ) phase of the cardiac cycle represents left ventricular stroke volume ( $Q_{1vs}$ ). Likewise left ventricular volume ( $Q_{1v}$ ),  $Q_{1vs}$  demonstrated a curvilinear increase during the last trimester of pregnancy (Fig. 6.6). The mean  $Q_{1vs}$  value for each week of pregnancy was therefore presented. Mean  $Q_{1vs}$

rose from 0.9 ml at 28 weeks to 2.8 ml at 40 weeks of gestation ( $p < 0.001$ ). From the antenatal-neonatal study there appeared to be a further increase in  $Q_{1vs}$  during the first 24 hours following delivery (Fig. 6.7), i.e. from 2.7 ml before, to 3.4 ml within 10 minutes after delivery ( $p < 0.01$ ), and up to 3.5 and 3.6 ml 4 hours, 24 hours and 48 hours later.

### 6.3.2 Left ventricular output ( $Q'_{1v}$ )

Left ventricular output ( $Q'_{1v}$ ) was calculated from the product of stroke volume and heart rate. Mean  $Q'_{1v}$  increased in a curvilinear fashion from  $125 \text{ ml min}^{-1}$  at 28 weeks to  $391 \text{ ml min}^{-1}$  at 40 weeks of gestation ( $p < 0.001$ , Fig. 6.8). A further marked increase in  $Q'_{1v}$  occurred within 10 minutes following delivery from 379 to  $467 \text{ ml min}^{-1}$  ( $p < 0.001$ , Fig. 6.9). In 19 patients fetal  $Q'_{1v}$  measurements were carried out within 7 days of delivery allowing calculation of fetal  $Q'_{1v}$  per kg body weight (Table 6.1). A mean volume of  $126 \pm 11 \text{ ml kg}^{-1} \text{ min}^{-1}$  was found. In 15 out of 19 patients there were also neonatal  $Q'_{1v}$  values available within 10 minutes following delivery. A mean volume of  $151 \pm 12 \text{ ml kg}^{-1} \text{ min}^{-1}$  was calculated (Table 6.1).

### 6.3.3 Left ventricular ejection fraction ( $\frac{Q_{1vs}}{Q_{1ved}}$ )

Left ventricular ejection fraction ( $\frac{Q_{1vs}}{Q_{1ved}}$ ) was obtained from the following formula:

$$\frac{Q_{1vs}}{Q_{1ved}} \% = \frac{Q_{1ved} - Q_{1ves}}{Q_{1ved}} \times 100$$

Antenatally (Fig. 6.10) there was a significant linear reduction in  $\frac{Q_{1vs}}{Q_{1ved}}$  from 60% at 28 weeks to 50% at 40 weeks ( $p < 0.001$ ).

During the neonatal period no marked changes in  $\frac{Q_{lvs}}{Q_{lved}}$  were observed (Fig. 6.11).

#### 6.3.4 Discussion

Since the changes at birth have a profound influence on the circulation, data on fetal and neonatal left ventricular stroke volume, output and ejection fraction will be discussed separately.

##### 6.3.4.1 Fetal left ventricular function

For a better understanding of fetal ventricular function, a short review of the fetal circulation will be presented.

##### 6.3.4.1a Fetal circulation

Most of our current knowledge of the fetal circulation was obtained from experimental work in the fetal lamb. The principle characteristics of the fetal circulation are the following:

- both parts of the heart work in parallel to drive blood from the great veins to the aorta via two shunts: the foramen ovale at atrial level and the ductus arteriosus at arterial level;
- both shunts have a low flow resistance;
- the systemic circulation has a low flow resistance as a result of a low parallel resistance in the placental circuit;
- umbilical venous return reaches the inferior vena cava partly via the ductus venosus (40-60%) and partly via the portal circulation.

With respect to the distribution of blood to the various parts of the fetal body, most data are presented as a fraction of the combined output of both ventricles, which seems

reasonable on the basis of the parallel function of the fetal ventricles. Venous return via the inferior vena cava provides about 70% of combined ventricular output and the venous return via the superior vena cava about 20%. Only very small amounts of return from the superior vena cava crosses the foramen ovale, whereas about 40% of the venous return via the inferior vena cava representing 30% of combined ventricular output crosses the foramen ovale into the left atrium. About 80% of the right ventricular output passes across the ductus arteriosus to the descending aorta (data derived from Rudolph and Heymann, 1974). Only about 20% of the right ventricular output goes to the lungs because of a relative high pulmonary resistance. This high resistance is mainly the result of low lung tissue  $PO_2$  (Dawes et al, 1953; Reynolds, 1956; Lauer et al, 1965). The placenta receives 40-50% of the combined ventricular output.

6.3.4.1b Left ventricular stroke volume ( $Q_{1vs}$ ), output ( $Q'_{1v}$ ) and ejection fraction ( $\frac{Q_{1vs}}{Q_{1ved}}$ )

In our own study both fetal  $Q_{1vs}$  and  $Q'_{1v}$  showed a 3-fold increase during the third trimester of pregnancy. In Fig. 6.12 both mean  $Q'_{1v}$  values and 50 percentile fetal weight values for male infants of primigravida (Tables of Kloosterman, 1970) have been plotted against gestational age. From this figure it can be seen that  $Q'_{1v}$  parallels fetal weight with advancing gestation. Similar observations were made in the fetal lamb between 60 and 147 days of gestation (Rudolph and Heymann, 1970). Considerable data are available on the actual ventricular output per kg fetal body weight. Table 6.2 demonstrates that the vast majority of ventricular output estimations were derived from the fetal lamb. Initially, measurements were carried out under acute circumstances in fetal lambs exteriorized from the uterus with umbilical-placental blood flow maintained (Dawes et al, 1954; Assali et al, 1965; Mahon et al, 1966; Rudolph et al, 1967). With

the employment of this set-up, combined ventricular output has been measured by either the Fick method (Dawes et al, 1954), indicator dilution curves (Mahon et al, 1966) or electromagnetic flow transducers (Assali et al, 1965). It has been demonstrated that exteriorization of the fetus from its intrauterine environment results in a progressive fall in umbilical blood flow both in the lamb (Heymann and Rudolph, 1967) and previsible human fetus (Rudolph et al, 1971). Chronically instrumented fetal lambs which were kept in utero offered data which could be considered nearer the physiological situation (Rudolph et al, 1974; Faber and Green, 1972; Kirkpatrick et al, 1975; Rudolph and Heymann, 1977; Anderson et al, 1981). Only two ultrasonic studies on fetal ventricular output have been reported in the literature (Winsberg, 1972; Wladimiroff and McGhie, 1981). Obviously ultrasound, being a non-invasive technique, provides only indirect information on cardiac function. On the other hand, because of its non-invasiveness it is the only technique allowing assessment of cardiac function in the human fetus under entirely physiological circumstances. The gestational age at which the ventricular output studies were conducted varied considerably between the different investigators. It is probably because of the different techniques of investigation, the variable physiological circumstances and the wide range of gestational ages that the estimated ventricular output figures show such little agreement.

Left ventricular output in the fetal lamb varies between 97 (Assali et al, 1965) and  $250 \text{ ml kg}^{-1} \text{ min}^{-1}$  (Kirkpatrick et al, 1973). The ultrasonically determined  $Q'_{lv}$  values ranged between 109 (Winsberg, 1972) and  $126 \text{ ml kg}^{-1} \text{ min}^{-1}$  (present study). Right ventricular output also showed a large variation from 138 (Assali et al, 1965) to  $327 \text{ ml kg}^{-1} \text{ min}^{-1}$  (Rudolph et al, 1974). This high value reported by Rudolph may be the result of a decreased right to left shunt due to a rise in left atrial pressure. This may be determined by the geometric influence of the flow probes on the left side of the heart.

In a number of fetal lamb studies only combined ventricular output values were presented. Combined ventricular output was calculated as being as low as  $235 \text{ ml kg}^{-1}\text{min}^{-1}$  (Assali et al, 1965) and as high as  $1080 \text{ ml kg}^{-1}\text{min}^{-1}$  (Rudolph et al, 1967). Another striking detail in these fetal ventricular output studies is the difference of opinion on the contribution of each ventricle to the total output. Right-to-left ventricular output relationship varied from equal (50%-50%, Mahon et al, 1966) to left ventricular preponderance (45%-55%, Dawes et al, 1954) or right ventricular preponderance (59%-41% by Assali et al, 1965, 60%-40% by Anderson et al, 1981 and 67%-33% by Rudolph et al, 1974). Based on these relationships and a mean  $Q'_{LV}$  value of  $126 \text{ ml kg}^{-1}\text{min}^{-1}$  in our study, an approximation of total ventricular output in the human fetus could be made. From Table 6.3 it can be seen that total ventricular output may be as low as  $229 \text{ ml kg}^{-1}\text{min}^{-1}$  and as high as  $382 \text{ ml kg}^{-1}\text{min}^{-1}$ .

If we accept that the proportion of total cardiac output distributed to the different parts of the fetal body and to the placenta is not essentially different between the human fetus and the fetal lamb, a total cardiac output of about  $250 \text{ ml kg}^{-1}\text{min}^{-1}$ , i.e. a 50%-50% right-to-left ventricular relationship, seems to be likely for the following reasons:

- in the fetal lamb, about 70% of the total cardiac output is directed to the descending aorta (Shinebourne, 1974) and 40-50% to the placenta (Rudolph and Heymann, 1975).
- based on a 50%-50% right-to-left ventricular relationship a similar flow distribution pattern was observed in the human fetus: blood flow in the descending aorta based on mean velocity profiles was estimated at  $170-185 \text{ ml kg}^{-1}\text{min}^{-1}$  (Wladimiroff and McGhie, 1981) and in the umbilical vein at  $110-120 \text{ ml kg}^{-1}\text{min}^{-1}$  (Gill and Kossoff, 1979; Eik-Nes et al, 1980).

The magnitude of the fetal cardiac output is impressive when compared with that in the adult at rest. Together with low resistance shunts like the ductus arteriosus and placenta,

the high fetal cardiac output may represent a compensatory mechanism of the circulation against the low oxygen levels of the fetal blood in order to meet the high metabolic demands of the fetal tissues.

#### 6.3.4.2 Neonatal left ventricular function

##### 6.3.4.2a Neonatal circulation

The haemodynamic changes following birth are primarily a result of changes in flow resistance in two vascular areas: the pulmonary artery and the placenta. With lung expansion and ventilation, there is a fall in pulmonary vascular resistance (Dawes, 1968; Rudolph et al, 1977). It was shown that physical expansion of the lungs with gas without oxygen produced a small drop in vascular resistance. The main effect was related to the increased  $PO_2$  (Assali et al, 1968; Heymann et al, 1967). Whether oxygen has a direct dilatory effect on the pulmonary vascular smooth muscle, or whether it stimulates the release of a chemical mediator, is not known. There is a possibility that kinins may be involved in the decrease in pulmonary vascular resistance after birth because bradykinin is a potent pulmonary vessel dilator in the fetal lamb (Campbell et al, 1968). Recent studies (Heymann et al, 1979) indicated that also  $PGE_1$  may be involved in the fall in pulmonary resistance. Severing the umbilical circulation implies abolition of the placental circulation which results in a rise in systemic vascular resistance. The changes just described will have pronounced effects on the circulatory pattern. Aortic pressure rises, pulmonary artery pressure drops, the flow direction in the ductus arteriosus reverses from left to right. Also the closure of the foramen ovale is effected by the reversal of the fetal right-to-left atrial pressure difference.

6.3.4.2b Left ventricular stroke volume ( $Q_{1vs}$ ), output ( $Q'_{lv}$ ) and ejection fraction ( $\frac{Q_{1vs}}{Q_{lved}}$ )

An increase in ventricular output has been described which was initially more pronounced for the right ventricle. However, due to the left-to-right shunt of well-oxygenated blood the ductus arteriosus closes and right ventricular output soon becomes virtually equal. Actual figures of ventricular output reported in the literature and obtained from the present study are given in Table 6.4. As in the fetus, ventricular output values measured in the early neonate varied considerably. An initial discrepancy in left and right ventricular output was found by Burnard (1966) in the human neonate. In our own study a significant increase in mean  $Q_{1vs}$  (2.7→3.4 ml) and in mean  $Q'_{lv}$  (379→467 ml min<sup>-1</sup> or 126→151 ml kg<sup>-1</sup>min<sup>-1</sup>) was noted. This increase may reflect not only the closure of the low-resistance placental circuit, but also the need for increased blood flow to the brown adipose tissue, which is responsible for the metabolic response (heat production) to the relatively cold extrauterine environment, in which the newborn finds itself immediately after birth (Dawes, 1968). If the aortic pressure rises from about 45→65 mmHg and the systemic flow from 126→151 ml kg<sup>-1</sup> min<sup>-1</sup> and given that the venous pressure remains unchanged, the systemic resistance will increase by a factor  $65/45 \times 126/151 =$  about 1.2. This is less than the factor 2 which one would expect on the basis of abolition of the placental circuit which is perfused by about half the combined cardiac output. This smaller than expected rise in peripheral resistance indicates vasodilation elsewhere in the neonatal circulation such as intestinal tract, kidneys, liver and the brown adipose tissue. Whereas  $Q_{1vs}$  stayed nearly constant during the remainder of the study period,  $Q'_{lv}$  demonstrated a slight fall which may be determined by the reduction of neonatal heart rate during this period. Left ventricular ejection fraction did not significantly change as a result of a fairly constant end-diastolic to end-systolic ventricular

volume relationship.

#### 6.4 Dynamics of the intraventricular septum

The dynamics of the intraventricular septum (IVS) are characterized by:

- the change in thickness during systole ( $\Delta T_{vs}$ ) which is expressed by the following formula:

$$\Delta T_{vs} \text{ (mm)} = T_{vsed} - T_{vses}$$

- direction of IVS motion relative to the left ventricular posterior wall during systole, measured at the level of the mitral valve leaflets.

##### 6.4.1 The change in IVS thickness during systole ( $\Delta T_{vs}$ )

Antenatally there was virtually no change in septal thickness (Fig. 6.13; mean value  $0.06 \pm 0.2$  mm), whereas neonatally an increase in septal thickness occurred during systole (Fig. 6.14) from 0.02 mm before delivery to 0.9 mm within 10 minutes ( $p < 0.01$ ) and 1.4 mm 4 hours following delivery ( $p < 0.01$ ).

##### 6.4.2 Direction of IVS motion relative to the left ventricular posterior wall during systole

The septal motion in healthy adults and neonates clearly suggests the contribution of septal contraction to left ventricular pump function. Study of septal motion may therefore indicate this function for the fetus as well. During the antenatal period (Table 6.5), in over half the cases (56%) no measurable septal motion during systole was observed. Septal motion towards the left ventricular

posterior wall (non-paradox) was noted in 34% and motion away from the left posterior wall during systole (paradox) was only observed in 11% of the cases. There was a fairly constant distribution of the three septal motion patterns with respect to gestational age. Only at 40 weeks there appeared to be a predominantly non-paradoxical septal motion pattern. Within 10 minutes following delivery (Table 6.6) septal motion was non-paradoxical in all neonates. At 48 hours only one neonate exhibited paradoxical septal motion.

#### 6.4.3 Discussion

No data on the change in intraventricular septal thickness during systole could be found in the literature. The lack of any change in intraventricular septal thickness during the antenatal study period suggests non-involvement of the intraventricular septum in the process of ventricular contraction and indicates functional uniformity of both ventricles.

A number of reports are available on the direction of intraventricular septal motion relative to the left ventricular posterior wall during systole as shown in Table 6.7. Although all results were collected from M-mode recordings, they substantially differ between the various investigators. Winsberg (1972) and Egeblad et al (1975) noted close to or even 100% non-paradoxical septal motion, whereas Kleinmann et al (1978) and we observed this type of motion in only 44 and 34% of the cases studied. Of interest is the close resemblance in percentage of paradoxical septal motion (14 and 11%) in the studies conducted by Kleinmann et al (1978) and ourselves. In the same studies absence of any septal motion was established in 42 and 55% of the fetuses. The occurrence of three different septal motion patterns under otherwise entirely normal physiological circumstances does not contribute to the supposition that non-paradoxical and paradoxical septal movement reflect left and right ventricular overload. Looking at the data for each week of gestation (Table 6.5),

there was no significant difference in the distribution of the three intraventricular septal motion patterns between 28 and 39 weeks. From 39 to 40 weeks there was, however, a shift from absent to non-paradoxical septal motion. This is more likely to be a coincidental finding rather than some sort of a mechanism being responsible.

The significant thickening of the intraventricular septum during systole which was observed soon after birth implies active involvement in left ventricular contraction. The direction of intraventricular septal motion relative to the left ventricular posterior wall during systole was always non-paradoxical during the first 24 hours following delivery. No structural or functional cardiac abnormalities were observed in the newborn which exhibited paradoxical septal movement 48 hours after birth. No further cardiac follow-up was carried out, and the infant subsequently developed well.

## 6.5 Summary

A. During the last trimester of pregnancy no significant changes in beat-to-beat interval (mean: 426 msec) were observed. There was a significant linear increase in left and right ventricular shortening indicating increasing circulatory demands associated with fetal growth as well as functional equality of both ventricles. Left ventricular stroke volume and cardiac output demonstrated a 3-fold rise, resulting at term in a mean value of 2.8 ml and 391 ml min<sup>-1</sup> (126 ml kg<sup>-1</sup>min<sup>-1</sup>) respectively. Total cardiac output in the term fetus would be about 255 ml kg<sup>-1</sup>min<sup>-1</sup> in case of a 50%-50% right-to-left ventricular output relationship. There is a reduction in left ventricular ejection fraction as a result of an increase in left ventricular volume which is larger in end-diastole than in end-systole. There is virtually no change in septal thickness during systole suggesting

non-involvement in the process of ventricular contraction. In more than 50% of the fetuses no measurable septal motion during systole was observed. Paradoxical septal movement only occurred in about 10% of the cases studied.

B. Postnatally, there was a significant rise in beat-to-beat interval during the first 4 hours following birth. Left ventricular shortening demonstrated a further rise during the first 10 minutes after delivery, probably to maintain or even increase stroke volume as a result of a larger blood supply. There was a further marked elevation of left ventricular stroke volume and cardiac output up to mean values of 3.4 ml and  $467 \text{ ml min}^{-1}$  ( $151 \text{ ml kg}^{-1} \text{ min}^{-1}$ ) within 10 minutes following delivery. This increase may reflect both closure of the low-resistance placental circuit and the necessary increase in blood flow to the brown adipose tissue in order to compensate for the heat loss in the newborn immediately after birth. Left ventricular ejection fraction did not change significantly. There is a pronounced thickening of the intraventricular septum during systole indicating active involvement of the septum in ventricular contractility. The septal motion is predominantly non-paradoxical.

## Chapter 7

### VENTRICULAR GEOMETRY AND DYNAMICS IN THE GROWTH-RETARDED FETUS

This chapter deals with cardiac ventricular geometry and dynamics in the growth-retarded fetus during the last trimester of pregnancy. As described for normal pregnancies ten consecutive cardiac cycles were evaluated. As has been mentioned in Paragraph 4.1, a technically acceptable M-mode was collected in 19 out of 25 subjects. A maximum time interval of 28 days between M-mode cardiac examination and delivery was chosen in order to allow cardiac data to be related to birth weight and fetal outcome in a reasonable number of patients. The introduction of this time interval resulted in 15 out of 19 patients available for further analysis. In 13 patients no obvious cause for the fetal growth retardation could be found. The remaining two patients were hypertensive, i.e. blood pressure readings of 145/95 or more were obtained on different occasions. There was no oedema or proteinuria. Other relevant data are presented in Table 7.1. Mean pregnancy duration was 34 weeks (range 28-38 weeks), the mean time interval between M-mode evaluation and delivery was 1.4 weeks (range 0-4 weeks). Mean maternal parity was 1.4 (range 0-5). Birth weight was below the 10th percentile in all 15 and below the 5th percentile in 10 of the newborns according to the Tables of Kloosterman (1970). In two newborns (nos. 10 and 14; Table 7.1) birth weight was situated below the 2.3rd percentile. Confirmation of growth retardation was obtained from ultrasonic measurement of fetal head and chest size in 14 out of 15 patients. In one patient only fetal biparietal diameter measurements (BPD) were carried out. Gruenwald (1963, 1966) and Naeye (1966) were the first to point out that the head-to-trunk relationship in small-for-dates is often essentially different from that observed in the normal-size infant. This changed relationship

is characterized by a limited reduction of brain weight as compared with a marked weight reduction of liver, lungs and thymus. These morphological observations resulted in measurements of trunk size (chest size, upper-abdominal size) in normal and complicated pregnancy (Hansmann et al, 1973; Campbell and Wilkin, 1975; Campbell and Thoms, 1977).

Table 7.2 presents the biparietal diameter (BPD), chest area and head-to-chest ratio data classified according to the percentile limits of the normal curves produced by Bloemsma (1978). From this Table it can be seen that the majority of the BPD values and all chest values were situated below the 5th percentile of the normal curve. The head-to-chest ratio was above the 95th percentile of the normal curve in 8 out of 15 patients. At the time of the M-mode cardiac examinations, normal fetal heart rate patterns were observed reflecting satisfactory fetal condition. The majority of the infants (13) were born in good health, i.e. an Apgar score at 1 minute of 7 or more. Two infants, nos. 14 and 15, were slightly depressed at birth: the Apgar score at 1 minute was 4 and 5, at 5 minutes 8. None of the newborns exhibited any congenital abnormalities.

### 7.1 Fetal cardiac geometry

Table 7.3 presents the end-diastolic and end-systolic values of the transverse diameter of the left and right ventricle, the right-to-left ratio of these ventricular diameters, the left and right ventricular volumes and the intraventricular septal thickness in all individuals.

In Figs. 7.1-7.10 these geometrical data are plotted in the respective diagrams, as presented in Chapter 5. In the majority of patients, the transverse diameter of both the fetal left ( $D_{LV}$ ) and right ventricle ( $D_{RV}$ ) during end-diastole and end-systole was slightly reduced, i.e. nearly all values

were situated below the linear regression line (Figs. 7.1-7.4). The right-to-left ventricular ratio ( $\frac{D_{RV}}{D_{LV}}$ ) of end-diastolic and end-systolic diameter was normal in all cases (Figs. 7.5 and 7.6). Left ventricular end-diastolic volume ( $Q_{1ved}$ ) was nearly always and end-systolic volume ( $Q_{1ves}$ ) always below the normal mean for gestational age (Figs. 7.7 and 7.8). The volumes were always reduced particularly after 33 weeks. The values for the intraventricular septal thickness (Figs. 7.9 and 7.10) showed a distribution pattern, which was rather similar to that observed for the left and right ventricular transverse diameter. The majority of the data was situated below the linear regression line, only a few clearly reflected reduced septal thickness both during end-diastole and end-systole.

## 7.2 Fetal cardiac dynamics

Individual data on fetal cardiac dynamics are presented in Tables 7.4 and 7.5. In Figs. 7.11-7.16 these functional data are plotted in the diagrams presented in Chapter 5. Beat-to-beat interval was not essentially different between small-for-dates and normal-size infants (Fig. 7.11). The same accounts for the left ( $\Delta D_{LV}$ ) and right ventricular shortening ( $\Delta D_{RV}$ ) values (Figs. 7.12 and 7.13) which fell well within the normal distribution pattern. All data on left ventricular stroke volume ( $Q_{1vs}$ , Fig. 7.14) fell below the normal mean values for gestational age. An overall tendency to reduced left ventricular function could also be detected in the left ventricular output ( $Q'_{1V}$ ) figures (Fig. 7.15). It is of interest to note that in 10 small-for-dates which were studied within 7 days of delivery, left ventricular output per kg body weight was not essentially different from that observed in a normal population (mean  $126 \pm 11$  (1 SD)). Finally, in 11 out of 15 small-for-dates, left ventricular ejection fraction ( $\frac{Q_{1vs}}{Q_{1ved}}$ ) was situated above the linear regression line (Fig. 7.16).

### 7.3 Discussion

No reports in the literature were found on ventricular geometry and function in the small-for-date infant. We assumed that the fetal growth retardation as observed in our study was most likely determined by decreased uteroplacental blood flow due to placental malfunction, since none of the newborns showed signs of congenital infections or defects. Moreover, serial fetal biparietal diameter (BPD) measurements which were carried out in 10 out of 15 patients pointed at a 'late-flattening' type of growth retardation. Experiments on rats (Wigglesworth, 1964; Winick, 1971) and rhesus monkeys (Hill et al, 1971) as well as pathologic findings in the human fetus (Gruenwald, 1963) suggest a relationship between the late-flattening type of fetal growth retardation and placental vascular insufficiency. In these studies, brain-to-body ratio was elevated suggesting a brain sparing effect. Indeed in 11 out of 14 patients who were ultrasonically monitored, head-to-chest ratio was increased, in 8 cases the ratio values were situated above the 95th percentile limit of the normal curve. The brain sparing effect is explained by the redistribution of blood within the fetus. This is because of peripheral vasoconstriction and cerebral vascular dilatation (Cohn et al, 1974) during chronic reduction of oxygen transfer in order to maintain the circulation through the brain and heart at the expense of blood supply to those tissues which, in the short run, are less vital for fetal survival. The results on cardiac geometry in the growth-retarded fetus suggest only a moderate reduction in fetal left and right ventricular size and intraventricular septal thickness, particularly when taking into account the birth weights below the 5th percentile. Only in a few cases could a marked reduction of septal thickness be established. If oxygen deprivation persists, the anaerobic metabolism of the fetus becomes gradually exhausted. This will lead to myocardial depression, decrease in ventricular force and output, hypotension and eventually fetal death. In our study, fetal heart

rate patterns at the time of the M-mode recordings were entirely normal, indicating a satisfactory fetal condition. This is supported by normal right-to-left ventricular ratio values, normal beat-to-beat intervals and normal shortening of the left and right ventricular transverse diameter on M-mode recordings. Although left ventricular stroke volume and output were to some extent reduced, particularly during the latter weeks of pregnancy, values per kg fetal body weight were normal. This demonstrates once more the close relationship between left ventricular output and fetal weight. Of interest is that preliminary data on blood flow in the descending aorta measured by a combined two-dimensional real-time and pulsed Doppler system as introduced by Eik-Nes et al (1980) showed fairly constant blood flow values per kg fetal body weight (Eik-Nes et al; Wladimiroff et al, 1981).

The significance of the rise in left ventricular ejection fraction ( $\frac{Q_{lvs}}{Q_{lved}}$ ) is difficult to interpret for two reasons:

- there is a wide distribution of the individual normal data;
- there is a lack of any relationship between the magnitude of the ejection fraction and the severity of the growth retardation: three out of five clearly elevated ejection fraction values originated from 'border line' small-for-dates, i.e. between the 5th and 10th percentile for weight related to gestation (pat.no. 1, 2, 3, 9 and 10; Table 7.4).

Finally, structural cardiac abnormalities occur more often in the small-for-date infants, particularly in the so-called 'low profile' type of growth retardation with symmetrical reduction of fetal head and body size. Cardiac examination of the small-for-dates should therefore not only be restricted to M-mode recording of the cardiac ventricles, but also encompass an extensive search for possible structural cardiac defects. A more detailed insight into the structural composition of the fetal heart has been obtained by Allan et al (1980) who related ultrasonic images of the fetal heart

to post mortem specimens. At present, a full analysis of the structural composition and functional capacity of the fetal heart should include the use of two-dimensional real-time equipment together with M-mode and pulsed Doppler facilities.

#### 7.4 Summary

- In the majority of small-for-dates, intrauterine growth retardation was of the 'late-flattening type'; the head-to-chest ratio was increased, indicating a brain sparing effect.
- Left and right ventricular transverse diameter and intraventricular septal thickness were generally slightly reduced.
- All small-for-dates demonstrated normal heart rate patterns at the time of cardiac M-mode recordings, indicating normal values for right-to-left ventricular ratio and shortening of the transverse diameter of both ventricles during systole.
- The slight reduction in left ventricular stroke volume and left ventricular output reflects reduced fetal weight rather than diminished ventricular function, since both stroke volume and output expressed per kg fetal body weight showed considerable agreement with the values observed in normal size infants.

## SUMMARY

### Chapter 1

Most of our present knowledge of fetal and neonatal cardiovascular anatomy and function is derived from chronic and acute lamb experiments. The disadvantage of these experiments is that many physiologic functions were influenced by the surgery and anaesthesia.

By using ultrasound techniques it is possible to study the human fetal and neonatal heart under physiologic conditions. In the study, described in this thesis, the possibility of using M-mode registration to accurately and reproducibly measure ventricular size and intraventricular septal thickness in fetal and neonatal hearts during various periods of the cardiac cycle was investigated.

If this is so, these M-mode registrations will lead to a greater insight into fetal and neonatal cardiac ventricular geometry and function under physiologic and pathophysiologic circumstances.

### Chapter 2

In this chapter some basic principles of ultrasound investigation, with particular reference to M-mode technique are described. The limitations of the M-mode technique are discussed in short. In this study a combination of single element and a line selection from a dynamic focussed linear array real-time system (Organon Teknika) was used.

The analysis of the M-mode registration using a computer system with a digital tableau and light pen (Bid Pad One) is extensively discussed.

### Chapter 3

The technique for obtaining an M-mode recording of the cardiac ventricles in the antenatal and neonatal period is discussed separately.

Comparison of the results from both periods is only permitted when the same angle and cross-section through the heart has been obtained.

The following parameters were measured to gather information about cardiac geometry and function during the antenatal and neonatal period:

- the end-systolic and end-diastolic transverse cross-section of the right and left ventricle in mm.
- the end-systolic and end-diastolic thickness of the intraventricular septum in mm.
- beat-to-beat interval in msec.

The accuracy and reproducibility of the measurements is discussed. The sources of error in the measurements are divided into systematic and random errors. The systematic error is inherent to the instrumentation and the finite beamwidth of an ultrasound wave. The instrumentation error is calculated at less than 0.1%. Due to the finite ultrasound beamwidth a constant underestimation is made, resulting in an error of approximately 10% in the volume calculations in this study.

The random errors are due to:

- transducer positioning
- structural movement
- experience of the investigator

Reproducibility of the measurements in both periods was established with the use of intra- and interobserver variation, and intra- and interpatient variation. It is concluded that the measurements obtained from the M-mode registrations are adequately reproducible.

## Chapter 4

The selection criteria of the pregnancies are stated. Uncomplicated pregnancy and fetal growth retardation are defined. Further, the statistical methods used to test the results of the cross-sectional study during the antenatal period, and the longitudinal study during the antenatal-early neonatal period are described.

## Chapter 5

In this chapter the results of normal ventricular geometry during the last trimester of pregnancy and early neonatal period are presented. During the third trimester there was a linear increase in the growth of the right and left ventricle. The transverse diameter of the ventricles is equal, both in the end-diastolic and end-systolic phase of the cardiac cycle.

The findings in the literature are not entirely concordant with those of this study. Closer examination of these findings indicate that discrepancies may be due to differences in investigative procedures.

Left ventricular volume showed an approximately four-fold curvilinear increase at the end of pregnancy. The volume was approximately twice as great in end-diastole compared with end-systole.

The intraventricular septum showed a linear increase in thickness, revealing no difference in thickness during end-diastole or end-systole.

Directly after birth there was a further increase in the transverse diameter and volume of the left ventricle, while the transverse diameter of the right ventricle showed a clear reduction, resulting from functional geometric and volume changes in both ventricles. After birth there was an increase in intraventricular septal thickness only during the end-systolic phase of the cardiac cycle.

## Chapter 6

This chapter contains the results of normal ventricular function in the last trimester and the first 48 hours after birth. The beat-to-beat interval did not change significantly during the third trimester of pregnancy. The right and left ventricle showed a linear increase in shortening probably due to increasing circulatory demands of the growing fetus.

The left ventricular stroke volume and cardiac output increased three-fold. Assuming an equal output of the right and left ventricle, the total cardiac output was  $255 \text{ ml kg}^{-1} \text{ min}^{-1}$  in the term fetus.

There was a reduction in left ventricular ejection fraction caused by the larger increase in volume during end-diastole compared with end-systole.

Intraventricular septal thickness remained nearly the same during systole which implied that the septum played no role during ventricular contraction. In more than 50% of the cases there was no clear septal motion during systole, while in 10% there was paradoxical motion.

During the first four hours post partum there was a significant increase in beat-to-beat interval. Within the first 10 minutes after birth the left ventricular shortening increased, as a result of higher stroke volume following larger blood supply. Termination of placental circulation and increased demands of blood flow to the various organs of the neonate resulted in a rise in left ventricular output within 10 minutes of birth. No significant change in the ejection fraction of the left ventricle was noted.

Post partum there was a clear increase in intraventricular septal thickness during systole, in contrast to the antenatal period. It may be concluded that the septum plays an active role in ventricular function after birth.

A review of various authors who have calculated antenatal

and neonatal ventricular function is given. The results of these authors may not be compared with the results of our study in view of the different methods applied.

## Chapter 7

This chapter deals with ventricular geometry and function in the growth retarded fetus in the last trimester of pregnancy. There is no information on this subject in the literature. Repeated measurements of fetal biparietal diameter revealed 'late-flattening' type of growth retardation in the majority of cases (10 out of 15 patients). In 11 of 14 patients the head-chest ratio was increased, suggesting a brain sparing effect. In general, the transverse diameter of the right and left ventricle and intraventricular septal thickness in the growth retarded group was less than in the group with normal growth.

All growth retarded fetuses showed normal heart rate in the investigation. This indicated normal fetal cardiovascular function, emphasised by normal values being found for right-left ratio, and shortening of both ventricular transverse diameters during systole. A reduction in left ventricular stroke volume and output points more toward lower fetal weight than decreased ventricular function. The values of left ventricular stroke volume and output per kg fetal body weight were closely related to those of fetuses with normal weight for gestational age.

## SAMENVATTING

### Hoofdstuk 1

Het merendeel van onze huidige kennis van de foetale en neonatale cardiovasculaire anatomie en functie is verkregen uit het chronische en acute lammeren experiment. Het bezwaar van deze experimenten is dat door de chirurgische en anaesthesiologische procedures vele fysiologische functies werden beïnvloed. Met behulp van ultrageluidsonderzoek is het mogelijk om het humane foetale en neonatale hart te bestuderen onder geheel fysiologische omstandigheden.

In het onderzoek, beschreven in dit proefschrift, werd een antwoord gezocht op de vraag of door middel van ultrasound M-mode registratie nauwkeurige en reproduceerbare metingen van de ventrikel grootte en intraventriculaire septum dikte van het foetale en neonatale hart kunnen worden verricht gedurende de verschillende periodes van de hartcyclus. Als dit zo is, draagt deze M-mode registratietechniek dan bij tot een groter inzicht in onze kennis van de foetale en neonatale cardioventriculaire geometrie en functie zowel onder fysiologische als pathofysiologische omstandigheden.

### Hoofdstuk 2

In dit hoofdstuk worden enkele basisprincipes van het ultrageluidsonderzoek, voornamelijk met betrekking tot de M-mode techniek, uiteengezet. In het kort worden de beperkingen van de M-mode techniek besproken. Voor het eigen onderzoek werd voor het vervaardigen van een M-mode registratie gebruik gemaakt van een combinatie van een single element techniek en een lijnselectie van een dynamisch gefocuseerd linear-array real-time systeem (Organon Teknika). Uitvoerig wordt ingegaan op de wijze waarop een M-mode registratie werd geanalyseerd.

Dit gebeurde met behulp van een computer systeem met een digitaal tableau en lichtpen (Bid Pad One).

### Hoofdstuk 3

Hierin wordt de techniek voor het verkrijgen van een M-mode registratie van de cardiale ventrikels in de antenatale en neonatale periode afzonderlijk beschreven. Vergelijking van de resultaten in beide periodes is alleen dan geoorloofd als de registraties zijn gemaakt door dezelfde doorsnede van het hart, ervoor zorg dragend dat de richting van de ultrageluids-bundel door het hart zowel antenataal als neonataal ongeveer gelijk is.

De volgende parameters werden gemeten met het doel om informatie te verkrijgen over de cardiale geometrie en functie gedurende de antenatale en neonatale periode:

- de transversale doorsnede in mm van de linker en rechter ventrikel in de eind-diastolische en eind-systolische fase van de hartcyclus.
- de dikte van het intraventriculaire septum in mm eveneens in de eind-diastolische en eind-systolische fase.
- het beat-to-beat interval in msec.

Vervolgens wordt ingegaan op de nauwkeurigheid en reproduceerbaarheid van de metingen. De foutenbronnen, inherent aan de meting, worden onderverdeeld in systematische en toevallige fouten.

De systematische fouten worden veroorzaakt door fouten in de instrumentatie, en fouten in de eindige bundelbreedte van een ultrageluidsgolf.

De fout in de instrumentatie wordt op minder dan 0,1% geschat. Tengevolge van de fout in de eindige bundelbreedte van de ultrageluidsgolf wordt een constante onderschatting in de metingen gemaakt; voor de volumeberekening in dit onderzoek betekent dit een fout, die geschat wordt op ongeveer 10%.

De toevallige fouten kunnen ontstaan door:

- transducerpositionering
- bewegende structuren
- ervaring van de onderzoeker

De reproduceerbaarheid van de metingen zowel in de antenatale als in de neonatale periode werd getoetst met behulp van de intra- en interobserver variatie, alsmede intra- en interpatient variatie in de eerder genoemde parameters. Uit de resultaten mag worden geconcludeerd dat de metingen verricht aan de M-mode registraties in dit onderzoek voldoende reproduceerbaar zijn.

#### Hoofdstuk 4

De criteria voor de selectie van de zwangeren worden besproken. De ongestoorde zwangerschap en de foetale groeivertraging worden gedefinieerd. Tevens wordt besproken op welke wijze de resultaten van het transversale onderzoek in de antenatale periode en van het longitudinale onderzoek in de antenatale-vroeg neonatale periode statistisch zijn getoetst.

#### Hoofdstuk 5

In dit hoofdstuk worden de resultaten vermeld van de normale ventriculaire geometrie gedurende het laatste trimester van de zwangerschap en de vroeg neonatale periode. Gedurende het derde trimester van de zwangerschap was er een lineaire toename van de groei van de linker en de rechter ventrikel. De transversale diameter van beide ventrikels was gelijk, zowel in de eind-diastolische als in de eind-systolische fase van de hartcyclus.

De bevindingen in de literatuur komen niet geheel overeen met de onze. Doch bij de beschouwing van deze gegevens blijkt dat de verschillende resultaten nauwelijks met elkaar vergeleken kunnen worden tengevolge van de wisselende onderzoekprocedures.

Het linker ventrikelvolume toonde een kromlijnige toename dat ongeveer het 4-voudige bedroeg aan het einde van de zwangerschap. In de eind-diastolische fase was het volume ongeveer twee maal zo groot als in de eind-systolische fase. Het intraventriculaire septum liet eveneens een rechtlijnige toename in dikte zien, waarbij er geen verschil was tussen de dikte in de eind-diastolische en eind-systolische fase van de hartcyclus.

Onmiddellijk na de geboorte was er een verdere toename in transversale diameter en volume van de linker ventrikel waar te nemen, terwijl de transversale diameter van de rechter ventrikel een duidelijke afname liet zien, veroorzaakt door functioneel geometrische veranderingen door volumeveranderingen in beide hartshelften. De intraventriculaire septumdikte nam na de geboorte alleen toe in de eind-systolische fase van de hartcyclus.

## Hoofdstuk 6

Dit hoofdstuk bevat de resultaten van de normale ventriculaire functie gedurende het laatste trimester van de zwangerschap en de periode tot 48 uur na de geboorte. Het beat-to-beat interval toonde geen significante veranderingen in het 3e trimester van de zwangerschap.

De linker en rechter ventriculaire verkorting nam rechtlijnig toe, mogelijk als een gevolg van de verhoogde circulatoire behoefte bij de groeiende foetus.

Het slagvolume en de output van de linker ventrikel liet een 3-voudige toename zien. De totale cardiac output bedroeg op basis van eenzelfde output van de rechter en linker ventrikel ongeveer  $255 \text{ ml kg}^{-1} \text{ min}^{-1}$  in de  $\bar{a}$  terme foetus.

Er trad een afname op van de linker ventrikel ejectie fractie als gevolg van een grotere toename van het volume in de eind-diastolische fase dan in de eind-systolische fase van de hartcyclus.

De intraventriculaire septumdikte bleef gedurende de systole

nagenoeg gelijk, hetgeen suggereert dat het septum geen rol speelt in het proces van de ventriculaire contractie. In meer dan 50% van de gevallen werd geen duidelijke septumbeweging gezien tijdens de systole, terwijl er in 10% sprake was van een paradoxale beweging.

Gedurende de eerste vier uur post partum was er een significante toename in het beat-to-beat interval. De verkorting van de linker ventrikel nam gedurende de eerste tien minuten na de geboorte verder toe ter vergroting van het slagvolume als gevolg van een grotere bloedtoevoer. Ook de output van de linker ventrikel steeg binnen tien minuten post partum, als gevolg van zowel het uitvallen van de placenta circulatie, als van een verhoogde behoefte aan bloedflow naar de verschillende organen van de neonat. De ejectie fractie van de linker ventrikel veranderde niet significant.

In tegenstelling tot in de antenatale periode was er post partum een duidelijke toename van de intraventriculaire septumdikte tijdens de systole waar te nemen, waaruit mag worden geconcludeerd dat het septum na de geboorte een actieve rol gaat spelen in de ventriculaire functie.

Een overzicht wordt gegeven van onderzoekers die zowel in de antenatale als in de neonatale periode ventriculaire functies hebben berekend. De resultaten van de verschillende auteurs mogen niet direct met de resultaten uit ons onderzoek worden vergeleken vanwege de verschillen in toegepaste methodieken.

## Hoofdstuk 7

Dit hoofdstuk behandelt de ventriculaire geometrie en functie in de groei-vertraagde foetus tijdens het laatste trimester van de zwangerschap. Over dit onderwerp zijn in de literatuur geen gegevens bekend. Herhaalde metingen van de foetale distantia biparietalis duiden in het merendeel van de gevallen (10 van de 15 patiënten) op het 'late flattening' type groei-vertraging. De hoofd-romp ratio was bij 11 van 14 patiënten verhoogd, hetgeen een hersen sparend effect suggereert.

In het algemeen waren in de groep van de groeivertraagde foetus in de transversale diameters van de linker en rechter ventrikel, en de intraventriculaire septum dikte kleiner in vergelijking met deze groep van de foetus met een normale groeisnelheid.

Bij alle groeivertraagde foetus was een normaal hartritme ten tijde van het onderzoek. Dit indiceert een normale foetale cardiovasculaire functie, temeer daar er normale waarden werden gevonden voor de rechts-links ratio en verkorting van de transversale diameters van beide ventrikels gedurende de systole.

De afname van het linker ventriculaire slagvolume en output wijst meer in de richting van een lager foetaal gewicht dan een verminderde ventriculaire functie, daar de waarden van zowel het slagvolume als van de output van de linker ventrikel per kg foetaal lichaamsgewicht overeenkwamen met de waarden zoals die werden gevonden bij de foetus met een normaal gewicht voor de duur van de zwangerschap.

APPENDIX

Tables and Figures from Chapters 5, 6 and 7

authors	ultrasound technique	scanning plane of the heart	gest.ag (wks)
