Published online: 08 Jul 2009.
Abstract  Infections with several members of the human herpesviruses are the cause of significant ocular morbidity. Of the human herpesviruses, HSV-1 is the most frequent cause of primary and recurrent eye disease. Despite the availability of effective antiviral treatment, recurrent HSV-1 infection continues to be the leading cause of corneal blindness in industrialized nations. This review recapitulates the current insights in the role of the virus and the intra-corneal T cell response involved in the pathogenesis of human HSV-1-induced keratitis.

Key words  Herpes simplex virus; Keratitis; Infection; Pathogenesis; Immune response

Human herpesviruses

Morphology and classification  Virions of *Herpesviridae family* have a characteristic morphology. An icosahedral capsid surrounds an electron opaque core in which double stranded DNA is located. The capsid itself is surrounded by a tegument and a viral envelope. The viral envelope is the outer surface of the virion in which virus-encoded glycoproteins, exhibited as spikes, are embedded (Fig. 1).

The overall size of the virions varies from 120–300 nm. The double stranded DNA genome ranges from 120 to 230 kilo base pairs (kb).

The genome of herpes simplex virus (HSV) or human herpesvirus type 1 (HHV-1), the prototype of the Alphaherpesvirinae, has a unique

The genome of herpesviruses (Fig. 2) consists of long double stranded linear molecules with several repeated and inverted sequences. The DNA has two stretches of unique sequences, one long (unique long sequence, U1) and one that is much shorter (unique short sequence, U0). Each of these long sequences is bracketed by shorter identical DNA repeats. The viral DNA contains terminal and internal reiterated sequences. Because of the variability in the number of these reiterations, the size of individual genomes may vary by more than 10 kb. The genome of her-
The family Herpesviridae comprises a group of ancient large DNA viruses that are widespread in the animal world, having mammals, fish, birds and reptiles as their host species. They are classified into three subfamilies α, β and γ, initially primarily on basis of tissue tropism and related pathogenesis, but to date largely on basis of DNA sequence homology. The characteristics of the human herpesviruses (HHV) are listed in Table 1.

The α-herpesviruses have a relatively variable host range, a relative short replication cycle, rapid spread in culture, efficient destruction of infected cells and tendency to establish latent infections in neural tissue. They include HSV-1 (HHV-1), HSV-2 (HHV-2) and varicella zoster virus (VZV; HHV-3).

The β-herpesviruses have a restricted host range. The reproductive cycle is long and the infection progresses slowly in culture. The infected cells frequently become enlarged (cytomegaly). Latency is established in lymphoreticular cells, kidneys and secretory glands. Human β-herpesviruses include cytomegalovirus (CMV; HHV-5), HHV-6 and HHV-7.

The γ-herpesviruses have a very restricted host range. Viruses in this group infect specific T- or B-lymphocytes, causing either a lytic or latent infection. Human γ-herpesviruses include Epstein-Barr virus (EBV; HHV-4) and HHV-8.

**Replication and Latency of Herpes Simplex Virus (HSV)**

HSV-1 is the prototype of the human herpesviruses. The lytic or productive cycle of infection starts with the attachment of virus particles to susceptible cells. This interaction requires sequential interaction between viral membrane glycoproteins and cellular receptors. Entry of virus mediated by fusion of the envelope and plasma membranes rapidly follows the initial attachment. Upon entry into the cell, the capsids are transported to the nuclear pores where DNA is released into the nucleus. Transcription of viral DNA takes place in the nucleus in an orderly program. The earliest genes expressed are the five HSV immediate-early genes (α-phase, 2–4 hours post-infection). They are important in priming the cell for further gene expression and mobilising cellular transcription machinery. This phase is followed by the early gene expression (β-phase, 5–7 hours post-infection): the expression of a number of genes either directly or indirectly involved in genome...
replication. Upon genome replication viral structural proteins are expressed in high abundance during the late phase (βγ phase, timing depends on viral DNA synthesis). Viral capsids assemble in the nucleus. They bud through the host cell nuclear and cytoplasmic membranes, becoming enveloped in the process. Viral proteins are synthesized in the cytoplasm. Some of the host glycoproteins are captured during the process and end up on the outer surface of the virion. Enveloped infectious virions can either remain cell-associated and spread to other cells via virus-mediated fusion, or can be released from the cell for reinfec-

tion. ‘Cell-to-cell’ spread has several important implications for the pathogenesis of the disease. Diseases induced by HSV are characterized by local spread and progression of lesions, thereby largely evading local immune surveillance and host mediated immune clearance.

One of the most striking properties of all herpesviruses is their ability to persist in an apparently inactive state for varying duration of time, referred to as latency. The cellular site of latency appears to be different from the primary tissue in which the lytic infection occurs. HSV combines this property with a tendency for neurovirulence. During primary infection, neurons innervating the infected mucosa are invaded by the virus. After initial infection the HSV ascends by retrograde axonal transport in nerve axons to the innervating sensory ganglia, in which the virus replicates for several days. Subsequently, one of two mutually exclusive events can occur, either viral replication with neuronal destruction, which can result in severe neurological devastation (myelitis or encephalitis), or establishment of a latent infection and neuronal survival (Fig. 3A). Latent infection is defined as a type of persistent infection in which the viral genome is present but infectious virus is not produced except during intermittent episodes of reactivation. During latency little or no virus protein is synthesized, although an untranslated virus transcript, the so-called latency associated transcript (LAT), is produced. Occasionally, latency is interrupted, and the virus reactivates as the result of provocative stimuli. These may include physical or emotional stress, fever, and exposure to ultraviolet light, immune suppression, menstruation and tissue damage. As a con-

sequence any local trauma can reactivate the virus and cause a manifest infection. Reactivated virus travels down the sensory nerve and spreads to and replicates in mucocutaneous epithelial cells, producing the characteristic symptoms (Fig. 3B). Recurrent HSV infections predominantly occur at the site of primary infection.

Latent infections persist for life in the innervating sensory ganglia. Studies of HSV-induced skin diseases reveal that HSV-1 is isolated principally from oro-labial lesions innervated by the trigeminal ganglia and that HSV-2 is frequently isolated from lesions in the genital areas innervated by sacral ganglia. However, in addition to these two major sites, HSV can cause latent infection in other sites of spinal ganglia. In addition to ganglionic or neuronal latency, however, there is evidence for persistence of HSV DNA in both the skin and the cornea. Expression of LAT, however, has not been detected in these peripheral sites.

Recurrent HSV infections are thought to result mainly from reactivation of the HSV strain (i.e. endogenous strain) acquired during primary infection. However, genotypic analysis of HSV isolates showed that a target organ is not immune to reinfection. The reported frequency of reinfection, with an exogenous virus referred to as HSV-1 superinfection, in large scale studies seems to be low. Recently, we have developed a new PCR method, based on the stability and strain-to-strain differences of reiterated sequences within the HSV-1 genome, to genotype HSV-1 strains without viral culture. Evaluation of this technique showed that it provides a discrimination rate of 92% of unrelated clinical HSV-1 isolates. Subsequent genotyping of sequential corneal HSV-1 isolates of 30 patients with recrudescent HSV-1 keratitis patients demonstrated that the sequential isolates of 11 out of 30 patients were genetically different, suggesting corneal HSV-1 superinfection in the inter-recurrence period. Furthermore, corneal transplantation was identified as risk factor for corneal HSV-1 superinfection. This finding suggested the possibility of donor-to-host transmission of HSV-1 through corneal grafting.

Ocular manifestations of human herpesvirus infections (Table 1) The pattern of clinical disease resulting from primary infection with human herpesviruses is largely determined by the virus involved, the portal of entry and the immune status of the host. Generally in the fully immunocompetent host both primary and recurrent infections cause mild or no symptoms. When clinical symptoms do occur, they range from the common fever blisters on the lip to more rare and severe infections of the central nervous system. An overview of clinical manifestations of HHV infections is given in Tables 1 and 2 and Figure 4. Immune compromised persons, e.g. transplant recipients, neonates and AIDS patients, are at increased risk for severe herpesvirus infections.

Of the eight human herpesviruses identified to date seven have been shown to have clinical implications for ocular infection. HSV-1 and VZV are the viruses that cause eye disease most frequently. Not only the eye proper, may be affected, also infections of the adnexae,

</table>
like the eyelid skin and lacrimal gland, as well as infections of the cranial nerves are possible. HSV-2 infections of the eye are relatively rare, with clinical manifestations identical to those of HSV-1.

Primary and recurrent HSV infections in immunocompetent patients predominantly present with vesicular or ulcerating lesions on skin or mucous membranes. The mouth and lips are the most common sites of HSV-1 infection. Reactivation of herpesviruses is common in the immunocompromised host, usually resulting in asymptomatic viral shedding or in progressive mucocutaneous infection. HSV can disseminate and cause diffuse visceral infection. Varicella, caused by primary infection with VZV, is a common childhood infection. Ocular involvement in varicella frequently occurs on the eyelids, whereas corneal involvement is uncommon. Recurrent VZV infection (herpes zoster) presents as a cluster of vesicular lesions, so-called shingles, which appear unilaterally in the dermatomal distribution of one or more adjacent sensory nerves. Herpes zoster ophthalmicus is a clinical syndrome involving the ophthalmic branch of the trigeminal nerve. Ocular complications occur in 50–72% of patients with herpes zoster.

**Fig. 4. Presentations of herpes simplex virus infections of the anterior eye segment.**
ophthalmicus.\textsuperscript{30} In case of VZV infections of the eye the same clinical manifestations as in HSV-1 infections are possible. In addition to these manifestations, postherpetic neuralgia and cranial nerve palsies may occur.\textsuperscript{31} Ocular disease caused by the reactivation of latent VZV is more likely to occur in the elderly and the immune compromised.\textsuperscript{32-33,34-35}

EBV is the most common etiologic agent of infectious mononucleosis.\textsuperscript{36} EBV is also associated with malignant disease, including different types of lymphomas and nasopharyngeal carcinoma.\textsuperscript{36,37} Ocular manifestations occur rarely in EBV infection. When present, they may encompass a wide range of clinical pictures, including infections of the anterior segment of the eye,\textsuperscript{38} neuro-ophthalmological syndromes\textsuperscript{39} and intra-ocular lymphoma.\textsuperscript{40}

Congenital infections with CMV primarily affect the reticuloendothelial system and the central nervous system (CNS), whereas acquired CMV infection in immune competent individuals is usually asymptomatic. Some patients, however, develop a syndrome resembling infectious mononucleosis. Progression to invasive organ disease is mainly seen in immunocompromised patients.\textsuperscript{41} Ocular manifestations are rarely seen in congenital CMV infections. Ocular involvement in CMV infections in the adult population is confined to immunocompromised patients. In this group CMV is a common cause of retinitis.\textsuperscript{42}

The more recently discovered human herpesviruses, HHV-6 and HHV-7 have been associated with febrile illnesses and the childhood disease, exanthema subitum.\textsuperscript{43} In immunocompromised patients the spectrum of disease is extended to solid organ infections and bone marrow depression.\textsuperscript{44} To date HHV-7 has not been associated with ocular disease. Clinically manifest infections with HHV-8 are predominantly seen in immunocompromised patients. This virus seems to resemble EBV in its possible oncogenic properties.\textsuperscript{45} In isolated cases HHV-6 and HHV-8 are associated with intraocular lymphomas.\textsuperscript{46}

**Epidemiology of HSV infections** Herpesviruses do not persist well on environmental surfaces, and infection needs direct inoculation into areas where they can replicate. The first line of defense against the virus is the keratin layer of the superficial epidermis, which prevents direct access of these viruses to cell-membranes. In the absence of keratin, for instance in mucous membranes, cells are more prone to be infected.\textsuperscript{37} HSV-1 can be transmitted following close contact with the secretions, skin, or mucous membranes of a person shedding virus. Infection occurs via the mucosal surfaces. Infections with HSV-2 are usually acquired through sexual contact.

Humans are considered to be the only natural reservoir of HSV. HSV infects its host generally in the first decades of life.\textsuperscript{4} Primary infections with HSV manifest clinically only in 1–6\% of the time\textsuperscript{46} and most episodes of clinical disease are manifestations of reactivation of HSV infection. Because only a third of the individuals who harbor HSV recognize disease symptoms during primary or recurrent infections, serologic studies are used to defining the prevalence of HSV infections in the population. Seroprevalence rates of HSV vary with age, sex, sexual behavior, socio-economic status and geographic location.\textsuperscript{49} In adult populations the prevalence of HSV-1 antibodies varies from 45\%\textsuperscript{50} to
Corresponding with seroprevalence 70–80% of healthy individuals have HSV-1 DNA in their trigeminal ganglion. There is a trend towards a decreasing incidence of HSV-1 infections in the developed world. Antibodies to HSV-2 are rarely found before ages of onset of sexual activity. There is a trend towards an increasing incidence of HSV-2 infections in both the developed and developing countries. Although most genital HSV infections are caused by HSV-2 infection, a recognizable and growing portion is attributable to HSV-1 infections.

Among recipients of organ transplants, transmission of viruses through donor tissues is a well recognized clinical problem. CMV is the most prominent example. Manifest infection may occur, besides from reactivation, by graft-to-host transmission of donor-derived virus as a result of transplantation. Though rare, there are reports demonstrating probable HSV transmission to seronegative organ transplant recipients. Corneal transplantation is the most common type of tissue transplantation in The Netherlands. It is usually a safe procedure with little associated morbidity. In 5–10% of these patients herpetic keratitis is the reason for penetrating keratoplasty (PKP). Herpetic keratitis recurs relatively frequently (10–20%) after PKP. After PKP for reasons unrelated to HSV infection patients may still develop herpetic keratitis in their graft, referred to as ‘newly acquired HSV keratitis after PKP’.

**Epidemiology of Ocular HSV-1 Infection**

Ocular HSV infections are mainly confined to the anterior segment of the eye, including the conjunctiva and the eyelids (Table 2). HSV appears to be the most common infectious cause of blindness in developed countries. In developing countries, where chlamydia conjunctivitis is endemic, it is only second to trachoma as a cause of corneal blindness. In malnutrition combined with measles infection, HSV keratitis is a common cause of bilateral corneal blindness in children in the developing world. Despite the common exposure to HSV, ocular manifestations are only observed in about 1% of those exposed. This may be an underestimation because presenting symptoms of blepharitis and conjunctivitis are mild, and the condition remains largely unrecognized. Only 5% of ocular HSV disease represent primary infections. Liesegang *et al.* reported an incidence of 8.4 first ocular HSV infections per 100,000

The overall prevalence of ocular HSV infection has been estimated at 149 cases per 100,000 person-years. The overall prevalence of ocular HSV infection has been estimated at 149 cases per 100,000 person-years. Blepharitis, conjunctivitis and epithelial keratitis are the most common symptoms of primary ocular HSV infections. The predominant form of recurrent disease is epithelial and stromal keratitis (Table 2). Disease is bilateral in 12–19% of cases. A history of epithelial keratitis is not a significant risk factor for recurrent epithelial keratitis, whereas previous multiple episodes of stromal keratitis markedly increase the probability of subsequent stromal keratitis. The interval between attacks shortens with time. Herpetic stromal keratitis is a leading infectious cause of blindness worldwide.

Penetrating keratoplasty (PKP) and HSV keratitis In the general population, ocular manifestations of HSV-1 infection can lead to unilateral blindness and as result an indication for PKP. Five to 10% of PKPs are performed for corneal opacities resulting from HSV-1 infection. PKP for HSV keratitis has a high rate of post-operative complications (Table 3). Epithelial recurrences are a major problem after PKP. Graft rejections contribute to graft failure to a larger extent in PKP for HSV than in PKP for reasons unrelated to HSV-1 infection. Recurrences of HSV keratitis after PKP and the rate of immunological graft rejection in these grafts can be reduced by antiviral prophylaxis when steroids are employed to prevent or treat graft rejection. However, the use of prophylactic antiviral therapy is largely based on experience in patients with recurrent HSV related eye disease who have not undergone PKP.

Newly acquired corneal HSV-1 infections after PKP The finding, that HSV-1 keratitis occurs after PKP in patients without a previous history of HSV keratitis, poses questions about the frequency and impact of this manifestation, about the mode of transmission in these patients, and which transplant recipients are at risk to develop this infection.

In a retrospective analysis among 2112 patients transplanted for reasons unrelated to HSV infection, 18 presented with HSV-1 epithelial keratitis.
lial keratitis in their graft.\textsuperscript{75} The incidence of newly acquired HSV keratitis after PKP was calculated to be 1.2 per 1000 person years, i.e. 14-fold higher than that observed in the general population.\textsuperscript{76} A recent study conducted in 25 patients with this clinical manifestation, indicated that the majority of them (n = 14) developed severe ocular complications resulting in social blindness of the infected eye within three years (L. Remeijer; unpublished observation). In most cases, the newly acquired HSV-1 infection occurs within the first two years after PKP, again suggesting a causal relationship between corneal transplantation and HSV-1 infection. Several possibilities as to the origin of the virus exist, such as reactivation of latent virus in the trigeminal ganglion, viral transmission through tear shedding, viral growth in the storage medium or transmission through the donor cornea. Infectious agents that have been shown to be transmitted following corneal transplantation include bacteria, fungi, Creutzfeldt-Jakob agent, hepatitis B and C viruses and rabies virus.\textsuperscript{77}

Transmission of HSV-1 through corneal transplantation has recently been demonstrated by genetic characterization of HSV-1 DNA isolated from a donor cornea before and after corneal transplantation.\textsuperscript{78} The DNA sequences were identical for both strains. The patient proved to be HSV-1 naive before the transplantation.

**Host immune response to HSV** Following a viral infection, the immune system will recognize the virus as a foreign entity and try to eliminate it from the host. At first, non-specific immune cells, including macrophages, polymorphnuclear cells (PMN) and natural killer (NK) cells, which are part of the innate immune system, are attracted to the site of infection. Secondly, a virus-specific immune response (i.e. adaptive immunity) develops in which both B and T lymphocytes are involved. This constellation of immune responses to the virus serves to protect the infected organism from disseminated viral disease and death.\textsuperscript{79}

**Innate immune response** The first line of defense against herpesviruses is formed by the innate immune system. This system consists of cellular and soluble components. Macrophages and PMN recognize viral antigens in a non-specific fashion and eliminate the virus by phagocytosis and subsequent intracellular degradation. Both cell types show a marked increase of uptake of virus when virions are opsonized by antibody or complement.\textsuperscript{80} The anti-viral effect of NK cells involves the lysis of viral infected cells and production of IFN-\(\gamma\) upon stimulation with other cytokines like interleukin 12 (IL-12). The recognition of a virus-infected cell by NK cells is mediated either by the opsonization of an infected cell by virus-specific antibody,\textsuperscript{81} or by antigen recognition independently of the histocompatibility complex (MHC).\textsuperscript{82} Herpesvirus infection results in down-regulation of MHC class I molecules at the surface of an infected cell, rendering the cell susceptible to NK cell killing.\textsuperscript{83} Low NK cell activity is linked with increased human sensitivity to disseminated herpesvirus infections, including those with HSV, EBV and CMV.\textsuperscript{81,82} Cells of the innate immune system are located
in large numbers at strategic sites in and behind the physical barrier of
the organism, or circulate through the body fluids awaiting attraction
to the site of infection by chemotaxis.

The complement system and cytokines/chemokines secreted by virus
infected cells and inflammatory cells, form the major soluble com-
ponent of the innate immune response to herpesvirus infection. Viral
infection directly stimulates the production of IFN α and β by infected
cells. Both IFN α and β inhibit viral replication, enhance the ability
of NK cells to kill infected target cells and facilitate antigen processing
and presentation by MHC. The secretion of various chemokines,
like IL-8, is induced at sites of viral infection providing a chemotactic
signal for immune cells to infiltrate the affected tissue.

This first line of immune defense facilitates an immediate response
to invading infectious agents, irrespective of the site of entry. Moreover,
it will limit dissemination of the virus, while at the same time the devel-
opment of a specific immune response in the draining lymphoid tissues
is initiated to combat the remaining virus and to build up immunolog-
ical memory.

Adaptive immune response Specific immune responses are
mediated by lymphocytes, recognizing the antigen by specific mem-
brane-bound antigen receptors. The adaptive immune response can be
divided into a humoral and a cellular immune response, mediated by
B and T lymphocytes, respectively.

Humoral immunity Virus-specific antibodies are important in the
defense early in the course of viral infection and in defense against
viruses that are liberated from lysed cells. Within several days after
onset of a herpesvirus infection, antibodies to some of the viral pro-
teins appear in the circulation. The major immunogens of HSV are the
viral proteins expressed at the cell surface of infected cells: the glyco-
proteins. Neutralizing virus-specific antibodies bind to envelope
proteins and prevent viral attachment and entry into host cell. Opsoniz-
ing antibodies may enhance phagocytic clearance of viral particles.
Secretory immunoglobulins of the IgA isotype, i.e. sIgA, may be impor-
tant for neutralizing viruses that enter via the mucous membranes and
trigger complement-mediated lysis of infected cells. Infectious cell-
free virus is mainly detected during primary infection. Herpesviruses
like HSV have a cell-to-cell spread and survive latently in the sensory
neurons, being inaccessible to antibodies after entry in the cell. In HSV
infection, antibodies do play a role in limiting dissemination the virus
from the primary site of infection to the innervating sensory ganglia
and other parts of the nervous system. Severe cases of herpesvirus
infections have been described in antibody deficiency syndromes, indi-
cating that antibodies are an important component in the immune
response to HSV infection.

Cellular immunity Severe HSV infections in patients with impaired T
cell immunity, e.g. AIDS patients and transplant recipients, indicate that
these cells play an important role in controlling viral infection. Both
virus-specific CD4+ and CD8+ T cells are mandatory in controlling her-
pesvirus infection. They distinguish virus-infected from non-infected cells by their T cell receptor, recognizing virus-derived peptides associated with MHC class II or I molecules expressed at the cell surface of infected cells, respectively. Following activation, T cells can kill infected cells or secrete cytokines. Based on their cytokine production profile, T cells can be divided into two groups: T1 and T2 cells. T1 cells mainly secrete IL-2, IFN-γ and TNF-α, whereas secretion of IL-4, IL-5 and IL-10 is restricted to T2 cells. The subgroup of T cells referred to as T0 cells secrete both T1 and T2 cytokines. In general herpesvirus-specific T cells responses are both T1 and T0-like.

**Immune Evasion** Herpesviruses have evolved numerous strategies that favor their own survival by evading host immunity. These strategies fall into two categories: indirect immunomodulatory effect of viral proteins by their interaction with the protein machinery of the host cell and the direct inhibitory effect of viral encoded proteins. Upon herpesvirus infection, virus-specific CD8+ T cell recognition is hampered by the low level of MHC class I expression on infected cells. Several herpesvirus proteins, like infected cell protein (ICP) 47 of HSV-1, have been shown to inhibit the assembly and cell surface expression of stable MHC class I molecules. Recently, ICP 22 of HSV-1 has been shown to inhibit CD4+ T cell responses. Additionally, herpesviruses are able to prevent apoptosis of infected cells. Some herpesviruses produce molecules that directly inhibit innate and adaptive immune responses. For example, human CMV encodes a protein (UL18), that inhibits T1/0 responses and is homologous to MHC class I proteins, which acts as a decoy for NK cells and an EBV protein, that shows homology to IL-10. Furthermore, three glycoproteins of HSV modulate the innate immune response by binding to complement factor 3b (gC) or the humoral response by binding to the Fc portion of IgG molecules (complex of gE and gI).

**Immunopathology** An immunopathogenic response is an immune response that causes tissue damage. This can occur when cells are destroyed with a limited regenerative capacity, or when repair deposits impair the function. Several mechanisms of immunopathology have been described. A consequence of persistent infection with some viruses is the formation of circulating immune complexes composed of viral antigens and specific antibodies. These complexes may become trapped in tissues and trigger inflammatory responses in which complement and PMNs play a major role.

During an immunopathogenic response the immune reaction changes focus with time, beginning with an appropriate antiviral response and spreading to encompass host antigens. Some viruses are known to contain amino-acid sequences that are also present in some self-antigens. It has been postulated that because of this ‘molecular mimicry’ antiviral immunity can lead to immune responses against self-antigens. The virus antigen should be different enough from host sequences to initiate an immune response, but similar enough that the response is cross-reactive. The resulting ‘anti-host’ response will then be maintained even after clearance of the virus. Alternatively, virus
infection may induce autoimmunity in the absence of shared antigens, a mechanism known as ‘bystander activation’.

**Herpesvirus keratitis**

*Corneal morphology and innervation* The cornea is the transparent tissue in the front of the eye that is primarily responsible for focusing light on the retina. The central cornea is about 0.52 mm thick. The tissue comprises five layers: epithelium, Bowman’s layer, stroma, Descemet’s membrane, and endothelium (Fig. 5). In the normal state the cornea does not contain blood vessels.

The corneal epithelium is a stratified squamous, non-keratinizing epithelium, approximately five cell-layers thick. Epithelial cells adjacent to Bowman’s layer can divide and renew the epithelial layer in two to four days. Epithelial wounds heal quickly over an intact Bowman’s layer. The Bowman’s layer is a very thin (8–10 μm) acellular zone beneath the epithelium. Bowman’s layer is often said to be resistant to trauma, offering a barrier to corneal invasion by microorganisms and tumor cells, but it is not known to which extent this is true. The Bowman’s layer is considered to have no regenerative capacity.

The stroma that constitutes about 90% of the cornea consists mainly of collagen fibrils, ground substance and keratocytes. The collagen fibrils of the cornea are uniform and small, about 250–300 Å in diameter. The ground substance surrounding the collagen fibrils is rich in glycosaminoglycans. The ground substance plays a role in maintaining the regular array of collagen fibrils. With stromal edema the individual collagen fibril does not change, the volume of the ground substance increases, and with this the space between collagen fibrils. The keratocyte is the predominant cell of the stroma, but accounts only for about 5% of the dry weight of the cornea. In response to stromal injury the keratocytes migrate into the wound area and undergo transformation into myofibroblasts. They contribute to the scar formation by proliferation and collagen production. The Descemet’s membrane is produced by the endothelium and approximately 10 μm thick. The endothelium is a monolayer of regularly shaped hexagonal cells, lying posterior on
Descemet’s membrane. The main function of the corneal endothelium is control of stromal hydration. This is essential for corneal transparency. Endothelial cells generally do not show mitotic activity. Cell density below a critical number (400–600 cells/mm²) is devastating for the transparency of the cornea.98

Sensory innervation of the cornea is supplied by the ophthalmic branch of the trigeminal nerve (ramus I, nervus V). The nerve fiber pattern of the cornea has been described as radially oriented nerve bundles entering the cornea from the sclera at the middle one third of its thickness.98 The nerves lose their myelin sheath after traversing 0.5–2.0 mm into the cornea and then continue as transparent axon cylinders. After passing Bowman’s layer, they ramify and end within the epithelium as free nerve endings.99,100 The nerve bundles in the subbasal plexus of the human cornea form a regular dense meshwork with equal density over a large central and mid-peripheral area101 (Fig. 6).

**THE CORNEA: AN IMMUNE PRIVILEGED SITE**

The cornea is considered to be an immune privileged tissue, in part because it cannot directly be accessed by the immune system:102 the cornea lacks blood and lymphatic vessels, structures that provide the conduit for transportation of immunologic components into and out of most tissues.103 The absence of blood vessels leads to sequestration of corneal antigens from the circulation. However, the normal cornea contains professional antigen presenting cells (APCs) such as dendritic cells and macrophages.104 Factors present in the normal cornea that contribute to immune privilege are IL-1 receptor antagonist and Fas ligand. Both are constitutively expressed and promote ocular immune privilege by different pathways.105,106 The cornea is in close contact with the fluid of the anterior chamber of the eye. Several mechanisms play a role in the

---

**Fig. 6. Sensory innervation of the cornea: the subbasal nerve plexus of the epithelium.**

immune privilege of the anterior chamber: blood-ocular barrier, the absence of lymphatic drainage from the intraocular structures, deviant host immune response after introduction of antigens (aqueous chamber associated immune deviation: ACAID) and soluble factors in the aqueous humor having a immunosuppressive effect on APC and T cells.

Although the cornea is an immune privileged site, the complete immune apparatus is present in the iris and at the limbus, a tissue that constitutes the zone between the cornea and surrounding conjunctiva. The conjunctiva has a rich lymphatic network arising approximately 1 mm peripherally from the limbus. During the course of inflammation Langerhans’ cells (dendritic cells) migrate from the limbus into the central cornea and the blood-ocular barrier can break down. In chronic inflammation the cornea becomes vascularized and thus the immune privileged state can be lost. Moreover, early in the inflammatory process, leukocytes extravasate from blood vessels in the limbus and migrate towards the center of the cornea.

**Corneal HSV infections: clinical features** HSV keratitis ranges from a superficial inflammation of the cornea to a complex ocular disease. It is usually initiated by the cytopathic effect of the virus and followed by inflammatory responses, which may affect all layers of the cornea. The ocular sequelae of HSV infections are determined by the frequency and duration of the recurrent disease episodes and the immunological response elicited. The four main categories of HSV keratitis are infectious epithelial keratitis (IEK), neurotrophic keratopathy, herpetic stromal keratitis (HSK), and endotheliitis. Each of these is subdivided into more specific clinical presentations (See Fig. 4).

**Infectious epithelial keratitis** The earliest epithelial lesions of HSV infection in the cornea are small vesicles in the epithelium, which have also been described as punctate epithelial keratopathy. Vesicles coalesce and a branching, linear lesion with terminal bulbs (swollen epithelial borders) develops, leading to the most common presentation of HSV keratitis: dendritic keratitis. The morphological features of epithelial HSV infection are in part due to contiguous cell-to-cell spread of the virus in the corneal epithelium restricted only by local immune surveillance. This ‘contiguous cell-to-cell spread’, however, does not explain the branching pattern of the dendritic corneal lesion: an almost circular corneal lesion would theoretically have been developed. It seems logical to postulate that HSV, with its affinity for neural tissue, causes lesions congruent with the anatomical pattern of innervating nerves of the target-organ. The nerve bundles in the subbasal plexus of the human cornea form a regular dense meshwork with equal density over a large central and mid-peripheral area. These nerve fiber bundles in the subbasal plexus run in the 9 to 3 hours direction just after penetrating the Bowman’s layer, then after the first bifurcation in the 12 to 6 hours direction and after a second bifurcation again in the 9 to 3 hours direction (Fig. 6). The branching pattern and the orientation of the dendritic lesion in HEK correlate with the
anatomy of the subbasal nerve plexus in the human corneal epithelium.\textsuperscript{115} In the borders of the lesion infectious virus may be present. As the disease process continues the center ulcerates and extends through the basement membrane.\textsuperscript{116} An enlarged dendritic ulcer, that is no longer linear, is referred to as a geographic ulcer. Another manifestation of IEK is the marginal ulcer. The proximity of the limbus leads to a rapid infiltration of leukocytes and neovascularization. The ulcer may lack the typical dendritic shape.\textsuperscript{117}

**Neurotrophic Keratitis** Multiple episodes of herpetic disease can result in structural injury to the Bowman's layer and corneal stroma. Early findings include irregularity of corneal surface and lack of normal luster. Punctate epitheliopathy may progress to a persistent epithelial defect, oval shaped with smooth grayish borders.\textsuperscript{109,110} Untreated or mistreated lesions may progress into ulceration, opacification, vascularization, and perforation of the cornea.

**Herpetic Stromal Keratitis** The corneal stroma may be affected as result of a corneal HSV infection through a variety of mechanisms. Stromal keratitis is a more severe and prolonged manifestation of HSV disease and occurs when the virus initiates a chronic corneal inflammation. It can be classified as immune stromal keratitis (ISK) and necrotizing stromal keratitis (NSK).\textsuperscript{109,110} These two manifestations are not mutually exclusive and probably a continuum.

Immune stromal keratitis may present as superficial stromal scarring or the so called ‘ghost scars’, deeper located infiltrative stromal keratitis. A rare form of ISK is a white ring shaped stromal lesion or the so-called immune ring. The inflammatory response results in cellular infiltrate, edema, neovascularization and corneal scarring as a result of fibrosis and tissue destruction.

The predominant feature of NSK is necrosis with tissue loss, often masked by edema in the active phase of the inflammation. The clinical picture can evolve rather quickly and is sometimes refractory to treatment. The edema and neovascularization are more pronounced compared to ISK. Corneal scarring often leads to irregular astigmatism that may strongly interfere with vision.

**Corneal Endotheliitis** Corneal endotheliitis is an inflammatory reaction at the level of the corneal endothelium. In isolated endotheliitis stromal infiltrate and neovascularization are absent. Patients characteristically have keratic precipitates (KP), stromal and epithelial edema, and mild iritis. HSV endotheliitis can be classified based on the distribution of the KP and the configuration of the overlying stromal and epithelial edema.\textsuperscript{109} The most common form is disciform endotheliitis. Diffuse and linear forms of endotheliitis are also observed.\textsuperscript{118,119} When inflammation persists or is left untreated, secondary neovascularization and scarring may occur. Chronic endotheliitis may lead to endothelial decompensation.

**Herpes Keratitis after Penetrating Keratoplasty** Herpesvirus infection in a corneal graft may present with the whole range
of manifestations as in non-operated eyes. Early after transplantation IEK may present as a large epithelial defect without the characteristic dendritic appearance.\textsuperscript{120} In addition to this, herpetic keratitis might present with the manifestations of an allograft reaction: from a linear endotheliitis resembling a Khodadoust line\textsuperscript{119} to a diffuse endotheliitis, indiscernible from a full blown graft rejection.\textsuperscript{120}

**Corneal HSV infections: diagnosis** Traditionally the diagnosis of HSV keratitis is based on history and clinical presentation, occasionally complemented by viral culture. Viral isolation in cell culture remains the standard for the detection of infectious virus. This technique is not always available in general ophthalmology practice. Viral culture is an insensitive technique, particularly for the isolation of HSV-1 from the deeper layers of the cornea. Cultures are only found positive in herpetic keratitis with an epithelial defect. The polymerase chain reaction (PCR) represents a sensitive research laboratory tool and has the advantage of detecting very small amounts of DNA or RNA. The detection of HSV DNA by PCR provides evidence for the presence of viral DNA, which not necessarily means the presence of infectious virus.

Many lesions may present with a dendritic or dendriform lesion, including the epitheliopathy seen in healing corneas after a dendritic ulcer, a healing corneal abrasion, and the early stages of acanthamoeba keratitis. In ISK many other causative agents of infection are possible. However, 66\% of unilateral ISK is caused by HSV.\textsuperscript{121} Other viruses causing ISK are VZV, EBV, mumps virus, rubella virus, measles virus and influenza virus. Tuberculosis, syphilis, acanthamoebiasis and onchocerciasis are other infections associated with ISK. The complete differential diagnosis of stromal keratitis is extensive and beyond the scope of this review. In severe necrotizing disease, the clinical picture can be suggestive of bacterial keratitis, with ulceration, dense neutrophil infiltration and necrosis. Differential diagnosis of unilateral corneal edema with a normal endothelium in the opposite eye should bring up angle closure glaucoma and iridocorneal endothelial syndrome. When KPs are the only presenting sign other causes of anterior uveitis are possible.

Additionally, HSV has been implicated in other diseases of the anterior segment (Fig. 4 and table 1). HSV DNA has been detected in the iridocorneal endothelial syndrome,\textsuperscript{122,123} in the aqueous humor during a period of intra-ocular pressure elevation in Posner-Schlossman syndrome\textsuperscript{124} and in idiopathic endotheliopathy.\textsuperscript{125,126}

**Corneal HSV infections: pathogenesis and implications for therapy**

**Infectious epithelial keratitis** IEK results from viral replication in corneal epithelium and destruction of corneal epithelial cells: cytopathic effect of the virus. The duration of viral replication in the cornea depends on viral factors, including viral load, virus strain\textsuperscript{127} and host factors like immune status.
The immune response in IEK consists of HSV-specific IgG and (s)IgA present in the tear film and corneal stroma, antibody-dependent cell-mediated cytotoxicity and HLA class I and class II restricted immune responses. In addition to the specific immune reaction, IFN-α/β production by the infected epithelial cells limits the spread of the virus and allows resolution of the lesion. These dendritic lesions heal without scar formation, when the epithelium is the sole tissue affected. As the disease process continues, the infection can extend through the basement membrane, into keratocytes in the superficial corneal stroma underlying the site of the lesion resulting in HSK.

In IEK topical application of antivirals accelerates the elimination of replicating virus from the cornea. In this phase of the disease the immune response is directed at limiting the spread of the virus. Interference with this immune response, for instance by corticosteroids, may favor the spread of the virus into the stroma.

Neurotrophic keratopathy HSV-induced neurotrophic lesions are neither infectious nor immunologic in origin. Neurotrophic keratopathy is a multifactorial disease. Impaired corneal innervation in combination with decreased tear secretion produces non-healing epithelial defects. Basement membrane damage and stromal inflammation interferes with normal epithelial wound healing.

The resulting damage should determine the therapeutic approach. Artificial tears in dry eye syndromes, protection of a vulnerable basement membrane by bandage contact lens, or low strength steroids in chronic stromal inflammation. The keratopathy may be exacerbated by the chronic use of topical medications, especially antiviral treatment and toxic antibiotics.

Herpetic stromal keratitis The permanent loss of vision associated with HSV-1 corneal infection is due to an inflammatory response in the corneal stroma. The immune response following an HSV corneal infection resembles that observed following HSV infection at non-ocular sites. While the immune response elicited by the infecting virus is essential for limiting viral spread, it can have detrimental effects on the function of the cornea.

Studies on HSK have greatly benefited from the availability of several experimental animal models of the disease. Following inoculation of HSV-1 on a scarified mouse cornea, the animal develops a delayed onset of corneal inflammation, a non-necrotizing form of HSK, that resembles many of the characteristics of recurrent ISK in humans. The only human specimens of active inflammation are those from necrotizing stromal keratitis. In immune stromal disease transplantation is preferably performed after inflammation has subsided.

Key events in the development of HSK involve the interaction between cornea infiltrating inflammatory cells and resident corneal cells. This interaction, in which macrophages producing IL-1 and TNF-α, and IFN-γ producing Th1 cells play a pivotal role, results in the local secretion of immune-modulatory factors including various chemokines.
HSK in the mouse is characterized by a bi-phasic cellular infiltrate of mainly neutrophils into the stromal layer. The first wave of neutrophils invading the cornea is only transient and is involved in viral clearance, whereas the second wave of neutrophils infiltration coincides with clinical manifestations of the disease. An essential factor for the development of HSK is the involvement of cornea infiltrating CD4+ cells with a Th1 phenotype. These cells orchestrate the extravasation and activation of infiltrating neutrophils during the clinical phase of the disease. Neutrophils are known to secrete several other chemokines with possible antiviral function like IFN-α, and TNF-α and nitric oxide. Production of Th2 cytokines, such as IL-10 and IL-4, detected in mouse corneas during the resolution phase, has been shown to inhibit HSK.

The Th1-derived cytokine IL-17 has been shown to play an important role in several inflammatory diseases characterized by massive infiltration of neutrophils into inflamed tissue. Recently, expression of IL-17 has been detected in corneas of NSK patients and activated intra-corneal T cell lines recovered from both ISK and NSK patients. Furthermore, human corneal fibroblasts (HCF) constitutively express the IL-17 receptor. IL-17 exhibited a strong synergistic effect with TNF-α on the induction of IL-6 and IL-8 secretion by HCF. Secreted IL-8 has a strong chemotactic effect on neutrophils. Additionally, IL-17 enhanced TNF-α and IFN-γ-induced secretion of macrophage inflammatory protein 1α and 3α, while inhibiting the induced secretion of RANTES. These data strongly suggest that IL-17 may play an important role in the induction or perpetuation of the immunopathologic process in human HSK by modulating the secretion of proinflammatory and chemotactic factors by corneal resident fibroblasts.

The antigen specificity of the corneal infiltrating T cells in HSK remains a mystery. There are several partially conflicting theories on the antigen specificity of these T cells involved in HSK as seen in experimental mouse models. Recent studies have provided evidence that HSK in the mouse represents an autoimmune response to corneal tissue. HSK could be induced by CD4+ T cells directed to an epitope derived from the HSV capsid protein UL6, which cross-reacts with an epitope of an antigen uniquely expressed in the murine cornea, so-called molecular mimicry. Another explanation for the presence and activation of intra-corneal CD4+ T cells, is that the T cell response results from exposure to cytokines in the infected cornea, referred to as ‘bystander activation’.

Only very few studies have addressed the antigen-specificity of cornea infiltrating T cells in HSK patients. In contrast to the experimental HSK model, replicating virus and viral antigens have been demonstrated in the corneas, during the active as well as the inactive phase of stromal keratitis in humans. HSV-specific T cells can be detected in corneas of patients with both active and quiescent HSK, in patients treated with steroids and also in HSV DNA-negative corneas. These studies demonstrated that virus-specific T cells can reside in the cornea for longer periods of time. In parallel to studies in the...
experimental HSK mouse model the role of auto-immunity in human HSK was analyzed. In none of the T cell lines (TCLs) generated from corneas of HSK patients, reactivity to UL6 or a soluble protein extract of human corneas could be demonstrated. These data suggest that the T cell response in HSK patients is directed to the initiating virus and not to a human corneal autoantigen or HSV UL6.156

Intra-corneal TCL obtained from HSK patients contain high numbers of HSV-specific T cells.158 Both CD4+ and CD8+ T cells are potentially involved in the intra-corneal HSV-specific T cell response. These data oppose results from studies performed in the experimental HSK mouse model in which corneal infiltrating T cells are predominantly of the CD4+ subset. Furthermore, the majority of the human intra-corneal TCL showed a restricted usage of T cell receptor Vβ domains.158

Antiviral treatment in ISK is both directed at the presumed presence of the virus and at prevention of severe reactivation of infection during steroid therapy. Topical antivirals should be used in a therapeutic dose. It has not been established that oral antiviral therapy is effective in acute stromal disease. However, visual acuity improved over 6 months in significantly more patients.159 The main indication for oral acyclovir in ISK is prevention of recurrent disease by a long-term low dose of acyclovir.160 Steroid therapy in stromal keratitis reduces the risk of persistent or progressive stromal keratitis by 68%, and leads to a significant shorter time to resolution.161 Steroid dosage depends on the severity of disease. In corneal disease it is rarely necessary to use dosages exceeding dexamethasone 0.1% six times a day. When edema and hyperemia are resolving tapering can be started slowly.

In case of NSK, both the viral replication and the severe immune response should be treated vigorously. Control of HSV replication should precede attempts to modulate the immune response. Both topical and systemic antiviral treatment should be used in high therapeutic doses, combined after two days with corticosteroid therapy.162

Corneal endotheliitis Endotheliitis probably results from lytic viral infection of the endothelium118,163,164 with release of infectious virus into the aqueous,165,166,167 In addition to lytic infection of endothelial cells, viral antigens may be expressed on the surface of infected cells. Immune competent cells may attack the endothelium, leading to enhanced damage. This process is probably analogous to the cellular immune response in ISK. Histopathologic studies in patients with acute endotheliitis are missing. The immune response is deleterious to the eye because the endothelium has no regenerative capacity. Endothelial dysfunction leads to stromal and epithelial edema. Treatment is similar to immune stromal keratitis.

Summarizing discussion The finding, that HSV-1 keratitis occurs after PKP in patients without a previous history of HSV keratitis,25 raises questions about the frequency and impact of this manifestation, about the mode of transmission in these patients, and about the numbers of transplant recipients at risk to develop this inflammatory disease. It is assumed that recurrent herpetic lesions are due to

Human HSV keratitis 275
reactivation of the strain acquired during primary infection. However, HSV-1 superinfection has been documented, but considered to be a relative rare event. Our data, however, demonstrate a high frequency of superinfection and suggest that PKP is a risk factor for corneal superinfection with HSV-1. Evidence is emerging that allograft rejection, primary graft failure, and endothelial cell loss of cultured eye bank corneas are associated with the presence of HSV-1 DNA (Table 3). Future research should be directed at assessment of the risk of transmission of HSV-1 through PKP the clinical impact of the infection on the patient’s vision. These questions are reminiscent of the situation with other herpesviruses in transplantation.

The immune response following an HSV corneal infection resembles that observed following HSV infection at non-ocular sites. While the immune response elicited by the infecting virus is essential for limiting viral spread, it can have detrimental effects on the function of the cornea. Currently, the mainstay of treatment in stromal herpetic keratitis consists of antiviral treatment in combination with steroids. Although the nature of the antigens recognized by the cornea infiltrating T-cells are still unknown, parts of the cascade of inflammatory responses are elucidated by studies in 'mice and man'. Development of new therapeutic strategies targeting specific HSK-associated cytokines/chemokines will be the challenge for the future to treat this sight-threatening disease more effectively.
