MicroRNAs (miRNAs) belong to an abundant class of highly conserved small (22nt) non-coding RNAs. MiRNA profiling studies indicate that their expression is highly cell type-dependent. Dicer1 is an essential RNase III endoribonuclease for miRNA processing. Hematopoietic cell type- and developmental stage-specific Dicer1 deletion models show that miRNAs are essential regulators of cellular survival, differentiation and function. For instance, miRNA deficiency in hematopoietic stem cells and progenitors of different origins results in decreased cell survival, dramatic developmental aberrations or dysfunctions in mice. We recently found that homozygous Dicer1 deletion in myeloid-committed progenitors results in an aberrant expression of stem cell genes and induces a regained self-renewal capacity. Moreover, Dicer1 deletion causes a block in macrophage development and myeloid dysplasia, a cellular condition that may be considered as a preleukemic state. However, Dicer1-null cells do not develop leukemia in mice, indicating that depletion of miRNAs is not enough for tumorigenesis. Surprisingly, we found that heterozygous Dicer1 deletion in myeloid-committed progenitors, but not Dicer1 knockout, collaborates with p53 deletion in leukemic progression and results in various types of leukemia. Our data indicate that Dicer1 is a haploinsufficient tumor suppressor in hematopoietic neoplasms, which is consistent with the observed downregulation of miRNA expression in human leukemia samples. Here, we review the various hematopoietic specific Dicer1 deletion mouse models and the phenotypes observed within the different hematopoietic lineages and cell developmental stages. Finally, we discuss the role for DICER1 in mouse and human malignant hematopoiesis.

Introduction

DICER1 is an evolutionarily conserved member of the RNase III family of endoribonucleases. The gene encoding DICER1 is located on human chromosome 14q32 and mouse chromosome 12E. DICER1 is a complex protein and contains three N-terminal Helicase domains (HEL1, HEL2i, HEL2), a DUF283 domain, which is presumably involved in binding of double-stranded RNA (dsRNA), a Platform domain, the pre-miRNA binding domain PAZ, RNase IIa, RNase IIIb and a C-terminal dsRNA binding domain (dsRBD).1-3 The RNase III domains of DICER1 cleave double-stranded RNA (dsRNA) substrates and specific precursor hairpin sequences, including so-called premiRNAs, into small 5’-phosphorylated RNAs of typically 21–23 nucleotides called miRNA.4 Deep sequencing of 5’-phosphorylated short RNAs in ES cells showed that the miRNA is the only class of short RNAs to be fully DICER1-dependent.5 However, the premature mir-451 is the single well-conserved miRNA-containing sequence known to bypass DICER1 processing and is matured by an Argonaute-2 (Ago-2)-dependent mechanism.6-9 The DICER1-generated short RNAs bind to Argonaute proteins in the so-called RNA-induced silencing complex (RISC). This complex induces degradation or inhibits translation of homologs target mRNAs.

Moreover RISC triggers gene silencing via chromatin modifications at target promoters under specific conditions such as cellular senescence.10,11 Genetic studies in plants, zebrafish and mice show that Dicer is essential for normal development.12-14 For instance, genetic deletion of Dicer in mice results in early embryonic mortality due to depletion of the Oct-4-positive pluripotent embryonic stem cell pool at embryonic day (E) 6-7.14 Dicer-null ES cells are incapable of processing miRNA hairpins or dsRNAs.5,15,16 However, Dicer is dispensable for the siRNA-mediated gene silencing response.10 Although a role for Dicer in centromeric silencing has been suggested, deep sequencing of small RNAs in Dicer-null and Dicer wild type ES cells indicates that the production of miRNAs is the sole catalytic function of Dicer in these cells.5 To bypass embryonic lethality and to enable investigation of Dicer functions in adult tissues in mice, a floxed Dicer allele (Dicerfl) has been generated that allows conditional deletion of Dicer in a cell type- and developmental stage-specific fashion.17 To address the overall role of miRNAs in the development and function of hematopoietic cells, different hematopoietic cell stage and lineage-specific conditional Dicer deletion strains have been used. First, we will review the phenotypic consequences of Dicer deletion at a later stage of T cell development (Fig. 1B). These mice show four major phenotypes: (1) Dicer is required for basic cellular processes, such as proliferation and survival, as also proposed by Cobb et al., and therefore Dicer deficiency results in decreased number of T-cells.18,19 (2) Dicer deletion appears to favor T-cell lineage production from CD4±CD8± double-positive stage toward CD4+ single-positive peripheral T-cells over CD8+ single-positive cells. However, this phenotype was less obvious from thymic T-cell lineage analysis. This discrepancy may be explained by the fact that CD4-Cre-driven deletion of Dicer does not result in complete depletion of all miRNAs, presumably due to high miRNA stability and limited cell divisions of a small fraction of CD4+ T-cells, which may be different for Dicer-null CD8± T-cells. (3) Dicer-null CD4+ T-cells produce increased levels of IFN-γ, a pro-Th1 cytokine, indicating that Dicer controls Th1-lineage commitment.19 (4) CD4-Cre; Dicerfl/fl mice show a more than 2-fold decreased proportion of Foxp3+ regulatory T cells (Treg).20 Interestingly, these mice developed a splenomegaly, and their lymph nodes were severely enlarged at the age of 3 to 4 mo. Moreover, organs such as colon, lung and liver were affected by immune pathology caused by an overactive immune system, which is less severe as compared with Foxp3-knockout mice lacking functional Tregs.20 However, this phenotype suggests that Dicer-deficient Tregs are functionally aberrant as well.

Two studies revealed the role of Dicer more specifically in the function of mature Tregs, using a Foxp3-Cre knock-in mouse (Fig. 1C).21,22 Under steady-state conditions, Foxp3-controlled deletion of Dicer has minimal effects on Treg cell development, cellular proliferation and survival in the peripheral compartments.22 However, a diminished fitness of Dicer-deficient Treg cells in the periphery was observed in a competitive experiment in mice.21 Under inflammatory conditions, the immune-repressive capacity of the mutant Treg cells is markedly reduced and results in rapid fatal autoimmunity and complete failure of immune suppression activity.21,22 Moreover, Dicer deletion in Treg cells leads to the progression of fatal lymphoproliferative autoimmune syndrome with an early onset, which is indistinguishably comparable to T-cell-specific Foxp3 deficiency.21 The expression of putative suppressor effector molecules, including CTLA4, IL-10, EBV-induced gene 3 (Ebi3) and granzyme B, was decreased by still-identified miRNA-controlled mechanisms.21 Tregs express a specific set of miRNAs, including mir-223, mir-155 and mir-146, which is distinct from naïve CD4+ T-cells.20 Therefore, the expression of these miRNAs may be under direct or indirect control of the transcription factor Foxp3.20 Identification of the targets that are controlled by these miRNAs in Tregs may provide new insights about the molecular pathways involved in the activity of these cells.

The role of miRNAs in invariant Natural Killer T (iNKT) cells was studied in a mouse strain by Tie2-Cre-mediated disruption of Dicer.23 The Tie2 kinase is specifically expressed in hematopoietic progenitors and endothelial cells.24 Similar to the immune phenotypes in CD4-Cre;Dicerfl/fl and Lek-Cre;Dicerfl/fl, these mice show reduced numbers of iNKT cells in the thymus, spleen and liver. Moreover, Dicer deletion results in developmental abnormalities of iNKT cells.23,25 In addition, Dicer-deficient peripheral iNKT cell numbers are decreased and displayed profound defects in α-GalCer, phorbol myristate acetate (PMA) and ionomycin-induced cellular activation and production of cytokines such as IL-4 and IFN-γ.23 Together, these data indicate that Dicer controls survival at the early T-cell developmental stage. At the later
stage, Dicer1 is critical for the balance of Th1/Th2 lineage production and controls functions such as immune-repression and specific cellular activity.

**Dicer1 Function During B Cell Development**

Ablation of Dicer1 in early B cell progenitors, mediated by the Mbi-Cre allele, which is expressed at the earliest stage of B-cell development, blocks B-cell development almost completely at the pro-B-cell (B220<sup>+</sup>, c-kit<sup>+</sup> CD25<sup>-</sup>) to pre-B-cell (B220<sup>-</sup>, c-kit<sup>-</sup>, CD25<sup>+</sup>) transition (Fig. 1D). This block in B-cell development is caused by a strong induction of apoptosis and results in total depletion of B cells in the BM and the peripheral lymphoid organs in mice. Gene expression profiling of Abelson virus (v-Abl)-transformed Dicer1-null pro-B-cells revealed that miR-142–3p and different members of the miR-17-92 family of miRNA, such as miR-17, miR-19, miR-20 and miR-92, are the most active at the pro-B-cell stage. Derepression of the proapoptotic protein BIM, a confirmed target of what has been observed in the Dicer1-deficient mice. The role of miRNAs in terminal B cell differentiation is addressed by the analysis of CD19-Cre driven Dicer1-deletion mouse model (Fig. 1E). In contrast to early Mbi-Cre driven Dicer1 deletion, deletion of Dicer1 with CD19-Cre in immature B220<sup>+</sup> IgM<sup>-</sup> cells does not induce cell death and allowed analysis of the role for Dicer1 in mature B cells in peripheral tissues. In the absence of Dicer1, transitional and marginal zone B cells are overrepresented, and the generation of follicular B cells is impaired. The miR-185 is abundantly expressed in follicular B-cells and controls the expression of B cell antigen receptor (BCR) signaling effector Bruton tyrosine kinase (Btk) in activated B cells. Dicer1-deficient B cells produce high titters of autoreactive antibodies and as a result cause autoimmune disease in aged female mice. However, the miRNAs that control autoreactivity are still unidentified.

To investigate the role for Dicer1 in antigen-activated, but not naive B cells, an activation-induced cytidine deaminase (Aicda)-Cre-mediated Dicer1 deletion mouse model has been generated. This mouse model showed that Dicer1 is required for the production of antigen-specific high-affinity antibodies during a T-cell-dependent immune response. Also, the formation of germinal center B cells is drastically impaired in Dicer1-deficient mice. These mutant mice fail to generate memory B and long-lived plasma cells after immunization with a T cell-dependent antigen. This study provides evidence for Dicer1-controlled cell proliferation of activated germinal center B-cells by strong repression of cell cycle inhibitory genes, such as Cdkn1c (p57<sup>Kip2</sup>), Cdkn2b (p16<sup>INK4b</sup>), Cdk1a (p21<sup>Cip1</sup>) and Cdkn1b (p27<sup>Kip1</sup>). Furthermore, Dicer1 deletion in B-cells leads to massive induction of apoptosis due to derepression of the proapoptotic protein BIM1 as described for early stages of B-cell development. Together, these data show that Dicer1 controls survival of B-cells at different stages of B-cell development, regulates cellular proliferation and is critical for proper B- and plasma cell functions.

**The Role for Dicer1 in NK Cell Function**

Bezman et al. induced ablation of conditional Dicer1 alleles with a tamoxifen-inducible Cre recombinase (human estrogen receptor (ER<sup>2<sup>)</sup>-Cre) and studied the effects of miRNA depletion in NK cells. This non-specific model revealed a role for Dicer1 in the maintenance of...
(HSPCs) was first studied by breeding Dicer1<sup>fl/fl</sup> with Mx-Cre mice. These mice express the Cre-recombinase in response to interferons and are highly efficient in recombination of floxed alleles in the hematopoietic system in vivo via peritoneal injection of polyI:polyC (pIpC). Dicer1 ablation in these mice depletes functional HSCs, induces rapid apoptosis in HSPCs and consequently causes total disruption of hematopoiesis. In addition, miRNA-depleted HSCs are unable to reconstitute hematopoiesis in mice. In full agreement, Dicer1<sup>fl/fl</sup> HSCs containing the VAVi-Cre transgene that is highly active in HSCs and efficient in deletion of floxed alleles are incapable to reconstitute lethally irradiated recipient mice (Erkeland SJ et al., unpublished data).

Together, these data show that Dicer1 is essential for HSCs survival. Interestingly, miR-125a controls the expansion of HSCs in vivo through targeting the proapototic gene Bak1. Whether miR-125a as a single miRNA can rescue Dicer1-null HSC survival and functions remains elusive, but it is more likely that multiple miRNAs are critical at this stage.

To address the question whether miRNAs play a role in early myeloid-lineage decisions, we deleted Dicer1 in CCAAT/enhancer-binding protein α (C/EBPA)-positive myeloid-committed progenitors in vivo (Fig. 2). In striking contrast to the results in HSCs and early lymphoid progenitors, we recently found that miRNA depletion does not affect the number of myeloid-committed progenitor cells in mice. However, isolated Dicer1-deficient granulocyte-macrophage progenitors (GMPs) were defective in myeloid development and exhibited an increased self-renewal potential. Dicer1 deletion in myeloid-committed progenitors revealed an unexpected function in hematopoiesis.

The consequences of Dicer1 deletion in hematopoietic stem and progenitor cells (HSPCs) was first studied by breeding Dicer1<sup>fl/fl</sup> with Mx-Cre mice. These mice express the Cre-recombinase in response to interferons and are highly efficient in recombination of floxed alleles in the hematopoietic system in vivo via peritoneal injection of polyI:polyC (pIpC). Dicer1 ablation in these mice depletes functional HSCs, induces rapid apoptosis in HSPCs and consequently causes total disruption of hematopoiesis. In addition, miRNA-depleted HSCs are unable to reconstitute hematopoiesis in mice. In full agreement, Dicer1<sup>fl/fl</sup> HSCs containing the VAVi-Cre transgene that is highly active in HSCs and efficient in deletion of floxed alleles are incapable to reconstitute lethally irradiated recipient mice (Erkeland SJ et al., unpublished data).

Together, these data show that Dicer1 is essential for HSCs survival. Interestingly, miR-125a controls the expansion of HSCs in vivo through targeting the proapototic gene Bak1. Whether miR-125a as a single miRNA can rescue Dicer1-null HSC survival and functions remains elusive, but it is more likely that multiple miRNAs are critical at this stage.

To address the question whether miRNAs play a role in early myeloid-lineage decisions, we deleted Dicer1 in CCAAT/enhancer-binding protein α (C/EBPA)-positive myeloid-committed progenitors in vivo (Fig. 2). In striking contrast to the results in HSCs and early lymphoid progenitors, we recently found that miRNA depletion does not affect the number of myeloid-committed progenitor cells in mice. However, isolated Dicer1-deficient granulocyte-macrophage progenitors (GMPs) were defective in myeloid development and exhibited an increased self-renewal potential. In mice, Dicer1 deletion by C/ebpa-Cre blocked monocytic differentiation, depleted macrophages and myelo-dendritic cells and caused myeloid dysplasia with morphological features of Pelger-Huet anomaly (Fig. 2). Strikingly, monocytes express low levels of proteins involved in miRNA processing and functions such as DROSHA, AGO1 and AGO2 compared with the levels found in T-cells, and are deficient for Dicer1, unless the cells are forced to differentiate toward macrophages. The presence of some miRNAs in the

---

**Figure 2.** Schematic overview of the results of C/ebpa-Cre-mediated deletion of Dicer1 in myeloid-committed progenitors. Phenotypic characteristics are indicated in red. In short, deletion of Dicer1 results in derepression of stem cell genes in myeloid progenitors and an enhanced self-renewal capacity. Furthermore, MDPs and GMPs are blocked in macrophage and dendritic cell development. In addition, Dicer1 deletion results in neutrophil dysplasia with cells that are characteristic for Pelger-Huet anomaly. HSC/LSK, hematopoietic stem cells/Lin-Scal1; Kit<sup>+</sup>; CMP, common myeloid progenitor; GMP, granulocyte-macrophage progenitor; MEP, megakaryocytic-erythroid progenitor; MDP, macrophage-dendritic cell progenitor; CD11B, pan marker for myeloid cells; GR-1, marker for mature granulocytes.
monocytic and Dicer1-deficient cell line U937 suggests that some miRNAs can be generated by proteins other than DICER1, such as PIWIL4, although this hypothesis still needs proper validation. However, the fact that Dicer1-null monocytes are blocked in their differentiation in vivo indicates that Dicer1 is essential at this stage, and its function cannot be bypassed by other miRNA processing mechanisms.

MiRNA profiling of wild type GMPs showed that 104 miRNAs are abundantly expressed at this stage, of which at least 20 miRNA families are potentially active by reducing their target miRNA abundance. Interestingly, of the derepressed miRNA targets in Dicer1-null GMPs, 27% are normally exclusively expressed in HSCs or are specific for multi-potent progenitors and erythropoiesis. Unlike the results from HSCs and lymphoid progenitors showing functions of Dicer1 mainly in survival pathways, these results provide evidence for a miRNA-controlled switch of a hematopoietic stem cell program of self-renewal and expansion toward myeloid differentiation (Fig. 2).

**The Role for Dicer1 in Leukemia**

Human cancer including different types of leukemia is characterized by a global reduction in miRNA expression. The first experimental evidence for a role of global downregulation of miRNAs in cellular transformation and tumorigenesis has been presented in a K-Ras-induced mouse model for lung cancer. Further studies of the role for Dicer1 in human cancer development in immune-deficient mice strongly suggested that Dicer1 is a haploinsufficient tumor suppressor. In this model, homozgyous deletion of Dicer1 is tolerated by the tumor cells; however, lack of miRNAs abrogates tumor outgrowth due to strongly reduced cell proliferation capacity of the DICER1-null cells. In agreement, heterozygous deletion of Dicer1, but not Dicer1-null knockout, accelerated tumor formation on a retinoblastoma-sensitized background. In mouse B-cells, Dicer1 is required for Myc-induced B-cell lymphomagenesis and survival of B-cell lymphomas. However, in this model Dicer1 is not a haploinsufficient tumor suppressor, as heterozygous deletion of Dicer1 does not affect lymphoma latency and overall survival. This discrepancy may indicate that the tumorsuppressing activity of DICER1 is cell type-dependent.

We asked whether Dicer1 deletion enhances myeloid leukemia development in mice. In hematopoietic cells, Clehpa starts to be expressed in early myeloid-committed progenitors, making it a suitable promoter to drive Dicer1 deletion for studying the role of miRNA depletion in myeloid leukemias. To circumvent prenatal lethality, we transplanted fetal liver cells from mutant and control embryos into lethally irradiated recipient mice. While heterozygous deletion of Dicer1 in myeloid-committed progenitors does not affect myeloid development, homozygous Dicer1 deletion results in block of macrophage/dendritic cell development and myeloid-dysplasia, a cellular condition that may be considered as a preleukemic state (Fig. 2). However, mice transplanted with either heterozygous floxed Dicer1 or homozgyous floxed Dicer1 cells survived devoid of any signs of myelo-proliferative disease or leukemia development within a year of observation, indicating that loss of Dicer1 in myeloid-committed progenitors is not sufficient to initiate short-term leukemogenesis in mice (Fig. 3A). To further investigate whether depletion of miRNAs accelerates myeloid leukemia development in a tumor susceptible model, we crossed Dicer1 floxed (Dicer1Δ) alleles with p53+/− mice and transplanted fetal liver cells from double mutants and control embryos into lethally irradiated recipient mice. Clehpacre driven deletion of p53 and hemizygous deletion of Dicer1 in mice caused development of various types of leukemias in half of the reconstituted mice with a latency of approximately 6 mo (Fig. 3). Only one out of eight Dicer1Δ:p53+/− recipient mice developed a leukemia with a latency of 9 mo (Fig. 3A). However, PCR analysis on genomic DNA isolated from the Dicer1Δ:p53+/− tumor cells in liver and spleen showed that the Dicer1 floxed alleles were incompletely recombined (Fig. 3B). These results are in full agreement with data published by Kumar et al. and strongly suggest that only reduced levels of Dicer1, but not biallelic loss of Dicer1, may play a functional role in leukemia development. However, the fact that total depletion of miRNAs does not affect the viability of myeloid progenitors in mice may suggest that no negative selection due to reduced survival or proliferation by lack of miRNAs occurs in these cells. Together, these data provide evidence for a model in which reduced level of miRNAs is an oncogenic event in the development of leukemia but that activity of at least some miRNA species is essential for oncogenic transformation (Fig. 4). This is in full agreement with experimental data showing tumor suppressing and oncogenic activities of investigated miRNAs, such as miR-17-92 and miR-125. Moreover, miRNA expression profiling data of human cancer and AML samples are consistent with this hypothesis, as a small subset of miRNAs, including e.g., miR-9, miR-125 and miR-17-92, are highly expressed, whereas most other miRNAs are downregulated.

**Dicer1 Mutations in Human Leukemia**

To date, the mechanism behind the reduced miRNA expression in subsets of human myeloid leukemia samples still remains elusive. One possibility is that the widespread silencing of miRNAs is the result of a defect in miRNA biogenesis caused by mutations in the gene encoding DICER1. For instance, data from Cancer Genome Project at the Wellcome Trust Sanger Institute (www.sanger.ac.uk/cosmic) show that somatic DICER1 mutations occur in different human tumors, including lung carcinoma, malignant melanoma and ovarian cancer. Recently, Hill et al. found DICER1 mutations in familial pleuro-pilmonary blastoma. In addition, a recent study in human non-epithelial ovarian cancers revealed mutations in the codons encoding metal-binding sites within the RNase IIIb catalytic centers of DICER1 in 30 of 102 (29%) of the tumors. These authors also detected mutations in 1 out of 14 non-seminomatous testicular germ-cell tumors, in 2 of 5 embryonal rhabdomyosarcomas, and in 1 of 266 epithelial ovarian and endometrial carcinomas. The RNA III domains of DICER1 are essential for miRNA maturation, and introduced mutations in the RNase IIIa and in RNase IIIb abrogate in vitro processing of the 3p and 5p miRNAs,
respectively. In agreement, transient expression experiments of mutant human DICER1 constructs in murine Dicer1-null mesenchymal stem cells showed that inactivation of the RNase IIIb domain by mutation of D1709, results in complete loss of, particularly, 5p-derived mature miRNAs, including the tumor-suppressive Let-7 family of miRNAs. This mutation is found in subsets of nonepithelial ovarian cancers. Indeed, the identified Dicer1 hot spot mutations in cancer result in reduced RNase IIIb activity but retain RNase IIIa activity, strongly suggesting a positive selection for the mutations that reduces Let7-tumorsuppressing activity in cancer development.

In a first attempt to gain more functional insight into the mechanisms behind the reduced miRNA expression in AML, a panel of 45 AML samples, characterized by activation of the oncogene EVI-1 due to t(3;3)(q21;q26) or inv(3)(q21q26) and poor prognosis, and five AML cell lines, including U937, MOLM1, MUTZ3, KASUMI-3 and F36P, were sequenced. In this panel of high-risk AML samples, no mutation in Dicer1 coding sequences and untranslated regions were identified (unpublished data, Erkeland S.J., Valk P., Delwel H., Sanders M.A., Groschel S. and Hoogenboezem R., 2012). Despite the limited set of data, this result suggests that other mechanisms are involved in deregulation of miRNA expression in human AML.

Different Mechanisms of DICER1 Activity Reduction in Human Leukemia

The expression of miRNAs may be deregulated by different mechanisms in human cancer. For instance, the activity of DICER1 may be reduced, as DICER1 is frequently deleted in various human cancers. In addition, low expression of DICER1 independently predicted poor outcomes in ovarian cancer patients. In chronic lymphocytic leukemia (CLL), low expression of DICER1 has been correlated with increased aggressiveness of the disease, shorter overall survival as well as reduced treatment-free survival. Notably, no such correlation between DICER1 transcript levels and disease...
outcome were found in human AML. However, there is evidence for regulation of Dicer1 expression by miRNAs such as miR-15a and miR-16 in a cohort of del(13q14) in CLL,52 miR-9 in Hodgkin lymphoma,54 miR-125 in human megakaryoblastic leukemia55 and miR-106a in the undifferentiated primary monocytess. Interestingly, miR-9, miR-125 and miR-106a are frequently aberrantly expressed at high levels in human AML,44,56 (and review49) and may control Dicer1 translation, leaving mRNA levels intact. Thus, aberrant miRNA biogenesis in human AML may occur via direct miRNA-controlled feedback mechanisms on translation of Dicer1 transcripts, but this hypothesis still needs proper experimental confirmation.

Reduction of miRNA expression may be controlled by other mechanisms as well. This hypothesis is supported by recently described mutations in the TAR RNA-binding protein 2 (TARBP2), a critical protein for processing miRNAs in sporadic and hereditary carcinomas, and the inactivating mutations in Exportin-5, which results in trap of pri-miRNAs in the nucleus in human cancer cells.57-59

Other possible mechanisms behind aberrant miRNA expression are single nucleotide polymorphisms (SNPs) that influence processing of miRNAs60 or RNA editing of miRNA precursors that blocks cleavage by Dicer1.61,62 Sequencing of factors of interest, we first crossed Cre;R26-LSL-Eyfp;Dicer1wt/fl mice. Fetal livers were obtained on embryonic day (E) 13.5. Genotyping of Dicer1; p53; Clebpa-Cre;R26-LSL-Eyfp embryos was performed by PCR assays of DNA from tail or foot biopsies. Sequences of primers are available upon request. All primers were obtained from Biologeo BV. For transplantation, 8-week-old recipient mice C57Bl/6, (Jackson Laboratories) were irradiated (8.5 Gy) and tail-vein injected with fetal liver single-cell suspensions. Typically, cells from each fetal liver were transplanted into two recipient mice. Tumorigenicity was subsequently monitored by daily examination of the transplanted mice. Mice were euthanized when moribund. All animal experiments were approved by the Animal Welfare/Ethics Committee of the Erasmus Medical Center.

Antibodies, cell staining, flow cytometry and cytopsins. Peripheral blood was obtained by heart puncture at the moment of euthanasia. Bone marrow cell suspensions were prepared as described previously.34 Tumor samples were prepared as single-cell suspension for cytopsins or FACS analysis. For morphological analysis of the cells, cytopsins were stained with May-Grünwald-Giemsa and examined with a Leica DMLB microscope (100x and 40x objectives) and Leica Application Suite software version 2.7.1 R1.

Figure 4. Model for the role of Dicer1 in leukemia development. Dicer1 knockout and as a result total loss of miRNA biogenesis, lead to myeloid dysplasia but not leukemia in a p53 knockout background. In contrast, heterozygous loss of Dicer1 conserves the expression of a set of miRNAs needed for normal differentiation. Furthermore, our model suggests that at least some miRNA activity is needed for oncogenic transformation.

Methods

Mice and reconstitution experiments.

To generate the different mouse lines of interest, we first crossed Clebpa-Cre;R26-LSL-Eyfp;Dicer1fl/fl mice with mice that contain floxed p53 conditional alleles (Jackson Laboratories). Finally, Clebpa-Cre;R26-LSL-Eyfp;Dicer1fl/wt; Dicer1fl/fl; p53fl/fl mice were obtained from breeding Clebpa-Cre;Dicer1fl/fl; p53fl/fl mice with R26-LSL-Eyfp;Dicer1fl/fl; p53fl/fl mice. Fetal livers were obtained on

In contrast, heterozygous loss of Dicer1 conserves the expression of a set of miRNAs needed for normal differentiation. Furthermore, our model suggests that at least some miRNA activity is needed for oncogenic transformation.

Conclusion

Recent data show that Dicer1 is an essential factor at different stages of normal hematopoiesis. A limitation of the Dicer1-deletion models is the global depletion of miRNAs that presumably results in disruption of many cellular pathways simultaneously, which hampers the identification of the functions of individual miRNAs. Although some studies show evidence for only a few miRNAs making dominant contributions, such as miR-17-92 in B-cell development, this may be different for other cell types or even be developmental stage-dependent. Overall, Dicer1 mainly controls survival and expansion at the early stages of lymphoid development and controls cellular activities at the terminal maturation stage. The function of Dicer1 is different in myelopoiesis at the earliest developmental stage as Dicer1 is not essential for cell viability but instead controls essential steps in switching from the stem cell stage toward myeloid lineage development. Although the functions of some miRNAs, such as miR-17/20/93/106 and miR-223, are well-described in immature and mature myeloid cells, respectively,56,63 the miRNA-controlled pathways that are involved at different stages of myelopoiesis are still largely elusive. Therefore,
tissue and developmental stage-specific miRNA-add-back in the Dicer1-deficient models and experimental target identification approaches may be of help for the understanding of the miRNA activities in hematopoiesis.

Acknowledgments

We thank Dr. T. Cupedo and Dr. M. Buitenhuis for critical reading of the manuscript and E. Simons for assistance with the preparation of the figures. We also thank Dr. K. van Lom for the microscopic analysis of leukemias. Our work was supported by grants from the Netherlands Organisation for Scientific Research (NWO-VENI) and the Dutch Cancer Society (KWF). There are no conflicts of interests.
